

Milroy Lectures

ON THE

INCIDENCE OF RHEUMATIC DISEASES.

Delivered before the Royal College of Physicians of London

J. ALISON GLOVER, O.B.E., M.D. CAMB.,

M.R.C.P. LOND., D.F.H.,

A MEDICAL OFFICER OF THE MINISTRY OF HEALTH.

LECTURE III.—THE INCIDENCE OF CHRONIC ARTHRITIS.*

(Delivered on March 4th.)

CHRONIC arthritis is in truth as old as the hills, for its effects have been recognised by Moëdic¹ in the seal skeletons of giant reptiles of the cretaceous æ, whilst long after this the cave bear and the brute-toothed tiger seem to have been especially subject to it, and it is still seen commonly in many *wer* animals. Nor in man is it any new disease; was as prevalent in the prehistoric dwellers of Nubia of Upper Egypt² as amongst our Saxon forefathers of the heptarchy of whom Prof. F. G. Parsons³ has told us, from the exploration of Saxon burial sites at argate, Mitcham, and Blidford-on-Avon, that they fared terribly from osteo-arthritis. Coming to more modern times Sydenham describes a chronic run of rheumatism lasting as long as life. Milton⁴ regards it as one of the worst of human ills. Of recent years, national insurance has shown its incidence to be of great importance.

The Registrar-General, using the international list of causes of death, classifies deaths from chronic rheumatic diseases under the heading 52, which is divided into three sub-headings: (1) chronic rheumatism, (2) rheumatoid and osteo-arthritis, (3) gout. The incidence, as shown by mortality statistics, must be regarded with due consideration to the fact that many of the sufferers are cut off by intercurrent causes, but this fact is to some extent compensated for by the method used by the Registrar-General in the classification of deaths. By their being placed in Group (IV. of the general diseases, a measure of preference is accorded to chronic rheumatism, osteo-arthritis, and gout, and, under the present method of working, they are preferred to almost any local cause recorded on the same certificate. This action tends to the completeness of the death returns in respect of chronic arthritis.

Before 1921, deaths from "chronic arthritis" were included under the heading "diseases of the joints," 50, and from 1921 to 1926 inclusive under the heading "chronic rheumatism" (52:1). They are now included under "rheumatoid and osteo-arthritis" (52:2). These changes have, however, not produced such effect; the diagnosis "chronic arthritis" seems to have been much less often used in death certification than chronic rheumatism or rheumatoid and osteo-arthritis. The total number of deaths recorded under category 52 in 1928 was 3318, of which 2774 (84 per cent.) were ascribed to rheumatoid and osteo-arthritis, 14 (0 per cent.) to chronic rheumatism, and 330 (0 per cent.) to gout.

The rise in the deaths ascribed to rheumatoid arthritis and osteo-arthritis is considerable; thus since 1918 the male deaths have risen from 382 to 785, in 1928 the female from 1129 to 1060—and both sexes over 1513 to 2774, an increase of 84 per cent. The category, originated in 1901 as "rheumatic arthritis, rheumatic gout," and 846 deaths previously allotted to "other constitutional diseases" were transferred

to it. The deaths ascribed to gout declined to 179 in 1923, since when they have risen to 330 in 1928, which is also an increase of 84 per cent.—an unexpected fact in view of the general impression that gout is a rapidly declining disease.

Probably, however, the increase in deaths due to rheumatoid and osteo-arthritis and to gout, though partly due to the older age-distribution of the population

FIG. 1.

Crude death-rates per million. Continuous line = acute rheumatism. Interrupted line = chronic rheumatism, rheumatoid arthritis and osteoarthritis, and gout.

and partly to the preferential selection in the Registrar-General's Office before mentioned, mainly comes from an increased accuracy of diagnosis, due to the increased attention that the chronic joint changes and their classification have received. The crude annual death-rates per million living show corresponding increases—rheumatoid and osteo-arthritis rising from 27 for males, 57 for females, and 44 for persons in 1918 (civil population) to 43 for males, 86 for females, and 70 for persons in 1928. The female death-rate from this group is thus twice as high as the male. More than twice as many deaths are now ascribed to the various forms of chronic rheumatism together than are ascribed to rheumatic fever (apart from heart diseases) and the whole category accounts for about 0.7 per cent. of deaths at all ages, and 1.013 per cent. of deaths taking ages above middle life (45 years) (Fig. 1).

CHRONIC ARTHRITIS IN HOSPITAL PRACTICE.

The small proportion of deaths ascribed to chronic arthritis in the death returns is, however, much larger than the proportion of all hospital admissions due to it. In four large London General Hospitals the proportions were as follows: Guy's (1920) 0.5 per cent. of all in-patients, 1.0 per cent. of medical in-patients; St. Thomas's (1925) 0.3 per cent. of in-patients; St. George's (1926) 0.2 per cent. of all in-patients; Royal Free (1928) 0.2 per cent. of all in-patients, 1.7 per cent. of medical in-patients. Even in special orthopaedic hospitals the admissions of chronic arthritis are very small—probably about 3 per cent.—and even in poor-law hospitals, where one would expect a higher percentage, it was found that only 1.8 per cent. of both sexes and 2.3 per cent. of females admitted for chronic arthritis. It is only in the spa hospitals, where some 40 per cent. of the patients are admitted on account of chronic arthritis, that any impression of the heavy incidence of chronic arthritis can be obtained from hospital admissions. As regards out-patients chronic arthritis cases amount to about 0.2 per cent. of all out-patients seen at general hospitals in London, although at the special massage and physiotherapeutic departments they form about 10 per cent. of the cases seen. At the special clinics for physiotherapy, the proportion of chronic arthritis rises to 15 per cent. at the Kensington British Red Cross Clinic, and 20 per cent. at the Edgar Allen Institute, Sheffield.

I have little information as regards foreign hospitals, but I have been informed that at the Mayo Clinic.

* Lectures I. and II. appeared in THE LANCET of March 8th and 22nd respectively.
5562

patients with chronic arthritis form some 7 per cent. of the total treated. Kroner² states that of a total of 3250 in-patients in the Municipal Hospital, Berlin, which correspond roughly to our poor-law infirmaries, 7 per cent. suffered from chronic arthritis.

A study of chronic disease in Boston was begun on June 1st, 1927, by the Boston Council of Social Agencies.⁶ A survey was made of 4316 chronic and incurable patients reported by Boston hospitals or social agencies, 1863 of whom were in hospitals for chronic diseases, 1043 in general hospitals, and 1410 under the care of the Community Association and other social organisations. Males totalled 46.2 per cent.; females 53.8 per cent. Nearly one-quarter were under 30 years of age, one-third between 30 and 60, and slightly more than half were ambulatory. Chronic arthritis cases numbered 467, or 11 per cent.; heart disease 845, or 19 per cent.; cancer 534, or 12 per cent. Kahlmeter,⁷ writing of Swedish Government invalidity pensions, says that next to old age infirmities chronic arthritis is the most frequent cause—i.e., in 9.1 per cent.—of all cases of permanent invalidity. Every year 1500 persons, out of a population of 6,000,000, are pensioned for permanent invalidity due to chronic arthritis. In Denmark⁸ 14 per cent. of 7297 persons in receipt of permanent invalidity pensions suffered from one or other of the different forms of chronic arthritis, as against 13.5 per cent. with pulmonary tuberculosis. Zimmer⁹ has, however, shown that in Berlin a tuberculous patient has 13.4 per cent. the chances of in-patient hospital treatment that a rheumatic patient has.

INSURANCE STATISTICS.

Fig. 4 of my second lecture showed the attack-rates for each age-group of chronic arthritis as a whole contrasted with those of fibrositis, and of acute rheumatism. Fig. 2 of the present lecture contrasts the attack-rates for each sex of all forms of chronic arthritis combined, whilst Fig. 3 shows the attack-rates for each form of chronic arthritis separately, and has many points of interest. The first—which

FIG. 2.

Incidence per thousand insured persons of each sex at each age group (England and Wales). Chronic arthritis, all forms.

I mentioned in my last lecture—is the increase in all diseases as age advances; the second, the suddenness of the rise at middle age (45). The third is the greater rates for females in every disease, except gout and in every age-group except in the group 35-44 in osteo-arthritis, and in the same group for all forms of arthritis. The fourth point is the almost complete absence of gout in insured women, gout being fifty times as common in insured men as in insured women.

It may be noted that this chart proves the last truth of the aphorism of Hippocrates¹⁰ that "a woman does not take the gout unless her menses be stopped."

As the greater incidence-rates fall upon the old age-periods in which there are fewer workers, results for all ages are not so bad as the very high rates in the over middle age periods would suggest. Allowing for the age-distribution of the insured

FIG. 3.

Incidence per thousand insured persons of each sex at each age group. A=rheumatoid arthritis. B=osteoarthritis. C=gout. D=unclassified.

population, we may estimate that in any thousand insured males of all ages there will be found one case of rheumatoid arthritis, three cases of osteo-arthritis, three cases of gout, and one case of unclassified arthritis. In any thousand insured females of all ages on the other hand, we shall expect (owing to the fact that insured females have a much younger age-distribution than insured males) three cases of rheumatoid arthritis and two of osteo-arthritis, gout being absent.

There were probably in the whole insured population in 1922 some 90,000 patients whose chronic arthritis was sufficient to make them seek medical advice for it during the year. In some 40,000 of these cases the disease would be severe, in 25,000 of moderate severity in 25,000 but slight or early. These estimates, of course, omit the much larger number of cases of chronic arthritis occurring in uninsured female population. Probably, too, if the sample were a fair one, the approved societies were paying to their members for that year sick or disablement pay for invalidity caused by chronic arthritis amounting to nearly £1,000,000 in something like these proportions—namely, for rheumatoid arthritis about £381,000, for osteo-arthritis about £389,000, for gout £145,000, and for unclassified chronic arthritis about £82,000.

Considerable as these attack-rates for osteo-arthritis may appear we must be prepared to enlarge our ideas about the incidence of osteo-arthritis still further if some modern views of fibrositis are accepted. The work of Putti and Sicard, for example, has largely modified continental opinion with regard to sciatica. Putti¹¹ is convinced that idiopathic sciatica takes origin in spinal arthritis, "that sciatica is a neuralgia

led by pathological conditions of the intervertebralamina and especially of the intervertebral articulations. In other words, sciatica is a symptom of iridocitis and lumbarthrititis. The terms rheumatica and idiopathic sciatica should be substituted the more precise and adequate one of arthritic or febrile sciatica. To treat the sciatica it is necessary to treat the arthrititis."

Allard¹² has recently stated that in America in the austrial cases of backache causing absence from work more than three months, 80 per cent. will be found to be due to hypertrophic arthrititis.

DIATHESSES AND SEX-INCIDENCE.

"The arthritic diathesis," says Llewellyn,¹³ "was tainly one of the first so-called diatheses laid down by our predecessors" and from early times most theories have inclined to the opinion that hereditary has a considerable part in the incidence of chronic arthritis—a part most strongly evidenced in gout;

but, perhaps, in rheumatoid arthritis; but still only played in osteoarthritis, which, like old and all its attributes, tends to run in families. Pemberton¹⁴ found a long family history in 10 per cent. of his patients, and considers it in certain families, especially those of anæmic or enteroptotic type, in whom one or two members had had arthritis, the occurrence in other members could be predicted almost certainly, especially at or around middle life. Strange¹⁵ found this strongly in his family history in almost all the same proportion as Pemberton, and the Ministry's inquiry¹⁶ among female patients with osteoarthritis was found in 48 per cent.

One might have thought Pemberton's families of asthenic or enteroptotic build would have been as likely to develop tuberculosis as rheumatoid arthritis, and it is strange to find, on the one hand, observers to say that persons with this arthritic diathesis are rigorously free from any tendency to pulmonary tuberculosis; Lawson Brown,¹⁴ for example, quoted by Pemberton, found only 11 cases of arthritis in 4500 cases of pulmonary tuberculosis. On the other hand, the Continent one form of rheumatoid arthritis ('onset's) is held to be due to a concealed focus of tuberculosis, such as a mediastinal gland.

In few diseases has sex a more pronounced influence on arthritis. Females are much more susceptible to rheumatoid arthritis than males—three as susceptible according to Strangeways, five times Llewellyn, and six times Bannatyne; concerning osteoarthritis the union is more divided. R. Stockman took the view that it is much more common in men than in women, but other observers speak in less certain terms, and in the Ministry of Health inquiry¹⁷ the attacks for osteoarthritis were found to be considerably higher for insured females than for insured men at every age above 45. Much will depend upon whether the observer classifies certain forms of climacteric arthritis as osteoarthritis. Monarticular osteoarthritis of the hip is much more common in men than in women; thus, it formed 8 per cent. of 149 male cases of osteoarthritis in the Ministry's practitioners' inquiry in 1922, and 9 per cent. of 640 male cases of

osteo-arthritis recorded by regional medical officers in the same year, whilst in female cases of osteoarthritis it formed respectively only 1 per cent. in 71 cases and 2 per cent. in 633 cases.

This sex inequality of incidence of malum coxae senilis is interesting when we recall that sciatica shows a similar sex inequality, being at least four times as common in men, whilst lumbago is thrice as common in men.

Monarticular osteoarthritis affecting one knee or one shoulder, on the other hand, form similar percentages of all cases of osteoarthritis in each sex—about 9 per cent. of all cases of osteoarthritis being cases in which one knee only is affected, and about 7 per cent. being cases in which the disease is confined entirely to one shoulder, whether the series of cases be males or females. Gout is perhaps of all diseases which can afflict both sexes the most exclusively masculine, and is perhaps 25 times as common in men as in women (my previous proportion relating only to

FIG. 4.

Shown by the percentages of patients in each age-group.

insured women). But in dealing with all forms of chronic arthritis together, and in such problems as provision of treatment, it will be well to estimate that there will be twice as many female patients as male.

The diagrams I have shown of attack-rates in various age-groups illustrate the effect of age upon incidence. Cases of rheumatoid arthritis may begin at 18 months or at 87 years¹⁸ but its onset is most commonly between 30 or 40 years—that is, a decade or a decade and a half before the usual age of 'onset' of osteoarthritis or gout¹⁹ as shown in Fig. 4. An earlier onset in rheumatoid arthritis than 30 is usually of serious prognostic import.

OCCUPATION AND CHILL.

Occupation has undoubtedly much influence upon the incidence of chronic arthritis, although its effects are as yet imperfectly understood. W. A. Lane has emphasised the influence of certain occupations in producing a condition, not so much the result of disease, but rather the result of a series of compensatory changes occurring in one or more joints in response to altered stress. J. van Breenem regards occupation as a determining factor in the production of arthritis, every special trade putting its mark upon what he calls the "rheumatic deviation." The joints most in use in the particular occupation generally show arthritic changes first, most, and longest; in his view

tional treatment. Such centres would be of the greatest service in many conditions other than arthritis, fractures and injuries, deformities, fibrositis, and diseases of the nervous system.

Last week was a memorable one in the history of the treatment of chronic arthritis, for it saw the opening by the Queen of the new Regent's Park Physical Treatment Centre for Rheumatic Diseases provided by the activity of the British Red Cross Society and the munificence of Sir Otto Beit and others. Without disparagement of several smaller existing clinics which are doing wholly admirable work in Kensington, Sheffield, and elsewhere, I may describe this new centre, capable of dealing with 400 patients a day, as the prototype of the new order. Unfortunately, no "arthritis unit" has yet come into being, and so far this institution remains a vision of the future.

Spa Treatment.

The *spa hospitals* of this country treat over 2500 cases of chronic arthritis each year, which form some 40 per cent. of all their cases admitted. They do an invaluable work now, but would do even better by proper coördination with arthritis units and physical treatment centres, for at present many of their 650 beds are occupied by patients whose disease is too advanced to permit of full benefit, and despite rules to the contrary, many patients come for spa treatment with unremoved focal sepsis. A wise selection of cases would be invaluable to the efficiency of the spa hospital. The patients having been thoroughly examined, and the preliminary treatment being completed at the arthritis unit, spa treatment would be more efficient and the chances of the spa physician to cure rather than to alleviate the condition of his arthritis patients greatly increased. Liaison with physical treatment centres would also enable a proper follow-up system to be introduced so that patients after leaving the spa hospital could be kept under periodic observation, and receive out-patient treatment when necessary.

In view of the heavy incidence of the chronic rheumatic diseases and their immense cost, the vision and support of all three types of institutions would scarcely fail to repay any reasonable expenditure upon them.

CEREBRO-SPINAL METASTASES FROM UNSUSPECTED PULMONARY CARCINOMA.

By FERGUS R. FERGUSON, M.D. MANCH.,
M.R.C.P. LOND.,

ASSISTANT PHYSICIAN, MANCHESTER ROYAL INFIRMARY; LATE
REGISTRAR, NATIONAL HOSPITAL FOR NERVOUS DISEASES;

AND

W. ESMOND REES, M.D., M.R.C.P. LOND.,
RESIDENT MEDICAL OFFICER, NATIONAL HOSPITAL FOR NERVOUS
DISEASES, QUEEN-SQUARE, LONDON.

UNTIL comparatively recently, primary carcinoma of the lung has been regarded as a somewhat rare disease. In 1903 Rolleston and Trevor¹ found only eight cases of intrathoracic malignant disease in 3983 autopsies extending over a period of 12 years. Investigations in this country, in America, and on the Continent during the past 10 to 15 years have revealed the fact that this disease is now much more frequent. During the period 1889-90 at the Eppendorfer Krankenhaus, Hamburg, Kikuth² states that there were only 10 primary cancers of the lung, whereas from 1912-23 there were 146 cases (the annual number of necropsies was doubled in the period 1889-1923). Primary carcinoma of the lung now probably constitutes about 4 per cent. of all carcinomata.

The problem naturally arises as to whether this increase is real or only apparent. Simpson³ has paid special attention to this point and concludes, after eliminating alterations in pathological conception and improvements in clinical diagnosis, that the increase in incidence is a real one. Many suggestions are forthcoming to account for this increase, but none of them is entirely satisfactory or free from criticism. It might be due to improvement in diagnosis, associated with recent advances in radiography and bronchoscopy, and to the attention which has been focused on the subject by the careful work of Barnard on the pathological nature of intrathoracic neoplasms. Fried⁴ has also suggested that influenza, recently present on several occasions in almost pandemic form, has been the direct cause of a metaplasia of the pulmonary epithelium leading to the development of a neoplasm. Other views are that the increase is due to the inhalation of some foreign material from the atmosphere (Duguid⁵), to "tar-spraying" of the roads or to the pollution of the air by exhaust gases from motor-driven vehicles.

Along with the increase in the primary lesion, one would expect an increase in the occurrence of secondary deposits, and the present investigation arose from the admission to the National Hospital for Nervous Diseases, Queen-square, during the past three years of eight verified cases of primary carcinoma of the lung associated with metastases giving rise to signs or symptoms of central nervous system involvement. The vigorous metastasising power of lung carcinomata has been noted frequently and has been attributed to the vascularity of the organ, to the frequent invasion of the blood-vessels by tumour, and to the abundant lymphatic channels. The frequency with which cerebral abscess follows bronchiectasis or pulmonary abscess is well known to every student, but the close association of pulmonary with cerebral carcinoma has received less attention in this country. The central nervous and osseous systems are much more frequently the site of secondary deposits from primary lung carcinomata than is generally recognised. A study of the post-mortem records of the National Hospital, Queen-square, shows that during the past ten years, out of a total of 29 tumours of which the secondary deposits produced signs or symptoms of central nervous system involvement, nine were of pulmonary origin.

This number was rivalled only by the cases of primary carcinoma of the breast, and in these the secondaries were chiefly in bone. In a recent article Weller* says: "The most noticeable omission from our series of cases is that of one illustrative of those who enter neuropsychiatric clinics because of changes dependent upon metastases to the brain or meninges." Dosquet* found central nervous system involvement in 37 per cent. of 105 cases of carcinoma of the lung; Fried* found 9 cases out of 10 lung carcinomata with cerebro-spinal symptoms. Although common, this association is not generally recognised, and the fact that, with one possible exception, it was not diagnosed in any of the present cases nor in many of the recorded cases is our excuse for emphasising it. The possibility of successful radical surgical treatment of the primary lung lesion and the advances in radium therapy increase the need for closer investigation and observation of these cases. The explanation of the difficulties probably lies in the fact that clinically the cases may present themselves in very diverse fashions.

First, there are the patients who show signs and symptoms of a chest lesion alone and in whom there is no ante-mortem evidence of cerebral metastases.

Secondly, cerebral symptoms may arise in the course of treatment for a pulmonary lesion. These cases are often found in a general or chest hospital; the neurological signs and symptoms are rather vague and indefinite and are probably attributed to toxæmia or cachexia.

Thirdly, there are the cases with which we are dealing where the chest signs are but few and receive scant attention, whereas the neurological signs and symptoms are prominent.

Fourthly, there are the few cases which die in coma without having previously presented any definite signs of pulmonary or nervous disease.

Since the clinical manifestations are so varied the problem obviously abounds with difficulties, especially as some of the most elusive medical problems are those which lie between two special departments—for example, pulmonary and neurological.

In the majority of the cerebral cases the symptoms are due to intracerebral deposits and in only a few to secondary pressure signs from cranial (bone) metastases. On the other hand, in the spinal group only seven or eight cases of true intramedullary secondary deposits have been recorded, and in the majority the symptoms result from pressure—either sudden or gradual in onset—from metastases in the vertebral column. Winkelman and Eckel* have noted a sharp clinical demarcation between the cerebral and spinal cases; Case 5 in our series is interesting in showing how cerebral signs and symptoms may arise from the extension of a vertebral lesion upwards to the base of the skull, so that a neurological picture like that of disseminated sclerosis or cerebro-spinal syphilis is presented.

Case Reports.

CASE 1, male, aged 37, was admitted in April, 1927, complaining of fits, headache, vomiting, and right-sided weakness of ten weeks' duration. In February, 1927, he noted, while driving a car, that his right leg was jerking. Many attacks of right-sided convulsions followed, usually heralded by twitching in the right buttock. He was well nourished and intelligent with hesitant speech. His right arm and leg were weak, hypotonic, ataxic, and defective in the sense of position and passive movement; the tendon-jerks in the right upper limb were exaggerated and the abdominal reflexes absent. The lungs were normal.

In May, 1927, a left parietal bone-flap was reflected, but no tumour was identified. Papilloedema, aphasia, and a right hemiplegia accompanied by marked emaciation preceded death in August, 1927.

Autopsy.—A large soft hernia, containing a tumour, was seen in the left parietal area and five tumours were found in the frontal, temporal, and occipital regions. The cerebellar hemispheres contained four tumours. All the tumours were rounded and clearly demarcated, frequently by a zone of hemorrhage and brain tissue. The superficial growths resembled small strawberries in colour and granularity (Fig. 1). A firm, whitish growth with many enlarged glands was found spreading outwards from the

root of the left lung; the left upper lobe showed a purulent broncho-pneumonia.

The spleen contained two large, white, rounded tumours; the other organs were normal. Microscopically, all the tumours presented very similar characteristics, although relative differences were present in the various organs. They consisted of trabeculae of large columnar cells, with their long axes parallel, and in the centre oval or rounded cells with comparatively little cytoplasm. The amount of fibrous tissue varied considerably; it was very pronounced in the centre of the hilar mass but only slight in amount in the brain, where the picture presented was that of trabecule

FIG. 1.

Horizontal sections of cerebral hemispheres (Case 1) showing secondary deposits, well demarcated, surrounded by a zone of hemorrhage, and, below, of "strawberry type."

of carcinoma cells with a central core of blood-vessels, the latter being immediately surrounded by a narrow zone of connective tissue (see Figs. 2 and 3).

CASE 2, male, aged 57, was first seen in November, 1927, complaining of loss of memory and drowsiness. Ten months previously he had had influenza (headache, drowsiness, and inversion of sleep rhythm); five months later he had pneumonia and pleurisy. The X ray taken at that time showed diffuse opacity at the base of the right lung, suggesting pleural effusion and thickening. He had been discharged from hospital in June, apparently well; shortly afterwards he had become very depressed, with poor memory and concentration. Later he had complained of weakness of the right arm and leg; this had improved but had recurred, together with incontinence of urine and faeces. He was pale but fairly well nourished, with a Parkinsonian facies but no speech defect; his cerebation was slow and his coöperation poor. His visual acuity, fields, and fundi were normal. All conjugate movements of the eyes, other than downward movement, were defective. He showed reversed Argyll Robertson pupils, and his tongue was tremulous and protruded with difficulty. The upper and lower limbs showed a generalised weakness and wasting, more marked on the right side. Apart from absence of the abdominal reflexes and a right extensor plantar response the reflexes were normal. Routine examination of the lungs revealed no abnormality. A presumptive diagnosis of post-encephalitic Parkinsonism was made, but a fortnight after admission he suddenly became comatose and died within 24 hours.

Pathological Examination.—The convolutions of the brain were markedly flattened; seven deposits were present in the pons and cerebellar hemispheres. The right lung

be immediately surrounded by a zone of connective tissue and small round cells, whilst more distally columns of large columnar cells, with vesicular nuclei, were arranged with their axes at right-angles to the vessel wall. There was considerable small round-celled infiltration in the fibrous tissue septa, which were not so well marked as in the primary pulmonary lesion.

CASE 9, male, aged 40, was admitted to hospital in April, 1929, with a ten days' history of left-sided Jacksonian attacks, followed by weakness of the left arm and leg. He had had a harsh cough for a week before admission but no previous history of chest trouble. He was dysarthric; his mentality was good and his pupils eccentric, reacting well to accommodation but sluggishly to light. Convergence and upward movement were impaired in both eyes; there was diplopia on looking downwards and to the right, and coarse, irregular nystagmus to this side. There was complete paralysis of the left lower face and weakness of the left trapezius and sternomastoid muscles, together with flaccid paralysis of the left arm and leg, an exaggerated left knee-jerk, absent left abdominal reflexes, and an equivocal left plantar response. The senses of passive movement, position and stereognosis were lost in the left hand. The respiratory system was normal. Two days after admission he was dyspnoeic, had intense pain in the left shoulder, and became much more drowsy. The percussion note was dull over the left lower lobe. Vocal resonance was impaired and the breath sounds were distant, but no adventitious sounds were heard. A week later these abnormal signs had disappeared, but the neurological condition remained unchanged. A few days later coma supervened, and he died on May 6th, 1929.

Pathological Report.—The body was emaciated. A white mass was found at the root of the upper lobe of the right lung. This lobe was oedematous and bronchiectatic; broncho-pneumonia was present at the base of the left lung. In the upper post-central region of the right cerebral hemisphere there was a rounded, soft, slightly hemorrhagic area of tumour surrounded by oedematous brain tissue. Microscopically the lung tumour was well demarcated; its cells, columnar in type, were arranged in trabeculae separated by strands of fibrous tissue. The typical arrangement of cells grouped around a central vessel was seen, but for the most part they were arranged irregularly in cluster formation; a considerable amount of hemorrhage was present. In the brain tumour the typical arrangement around a blood-vessel was well seen. The cells were larger than those in the pulmonary tumour; the nuclei were oval and vesicular. Fibrous tissue was scanty, but there was a considerable amount of hemorrhage.

Clinical Discussion.

In part, the object of this investigation has been to determine whether careful examination of a series of secondary brain tumours from a primary lesion—for example, a carcinoma of the lung—would reveal a typical clinical picture or metastatic syndrome, the knowledge of which would have enabled an ante-mortem diagnosis to be made. As already pointed out, the relative part played in the clinical picture by the lung and brain lesions varies considerably in different cases. Hence attention has to be paid, on the one hand, to the signs and symptoms of the pulmonary neoplasm and, on the other hand, to the results of the secondary deposits; it will be remembered that we are here dealing with the third group mentioned in the introduction. The above case reports have been carefully scrutinised and an especial note has been made of the following points.

Sex.—All the patients in this series were males. The predominance of the occurrence of pulmonary carcinoma in the male sex is such a striking feature that it attracts the attention of all investigators.

Occupation.—Many authors have assumed that the increased incidence of pulmonary carcinoma in recent years and its prevalence in the male sex must in some way be connected with occupation. The Schneeberg miners in Saxony, where various metallic substances are present in the dust in the mines, are especially liable (Arnstein).¹⁰ Hudson¹¹ noted a high incidence in grooms and suggested the frequent exposure to the inhalation of dust as the causative factor. Duguid⁶ found that labourers formed the largest percentage (28 per cent.) of affected workmen following one occupation; the suggestion is also made that the increase is due to tar, which is used so much more now than formerly for road-spraying (Staehelin¹²). The occupations of our

patients were—insurance agent, dairy manager, printer, labourer, clerk, motor-driver, tram conductor, and secretary. None of these occupations would appear to be of any aetiological importance.

Age.—The youngest patient in this series was 21 and the oldest 57; the average age was 42 (six of the nine patients were over 40). In Simpson's¹ series of 130 cases the average age was 48. This is rather above the average age incidence of cerebral tumours in general; in Tooth's series¹³ the average age of all tumours was 35–40. We note, however, that 50 per cent. of the last 20 cases of primary frontal tumour admitted to the National Hospital were over the age of 40 when their symptoms commenced. Thus, although it is frequently stated that metastatic deposits from a primary pulmonary lesion occur late in life, the above figures must be borne in mind before attaching undue importance to this factor.

Previous History.—Shennan¹⁴ thinks that the presence of old-standing disease (tuberculosis, chronic interstitial pneumonia) in at least 13 out of 22 primary carcinomata of the bronchus or lung cannot be ignored and must be regarded as possibly influencing the onset of the neoplasm. In eight out of our nine patients there was a history of some definite respiratory abnormality—bronchial asthma, pain in the chest, dyspnoea, persistent cough—or a lesion was suspected in the chest as the result of routine examination. In comparison, 7 only of the last 40 cases of cerebral tumour admitted to the National Hospital, Queen-square, gave a history of any respiratory abnormality and in none of them was a chest lesion suspected. Yet, despite the positive history, a presumptive diagnosis of a primary lung tumour with secondary cerebral metastases was made in only one case. Closer attention should be paid in doubtful cases to a history of respiratory abnormalities, and a more thorough clinical and radiographic examination of the thorax should be made.

Duration of Symptoms before Admission.—This varied from ten days to six months with an average period of about three months. The average duration of symptoms of cerebral tumours in general before coming under observation is longer than this. In the present series, the average total duration of illness was six months and the shortest period two months.

Mode of Onset.—Neurological symptoms were the first manifestation of disease in five cases, whereas chest and neurological symptoms appeared almost simultaneously in four. Of the seven patients in whom cerebral symptoms were the first or simultaneous manifestations of disease, in three the first complaint was of a psychological change; in two, Jacksonian attacks occurred and in two the symptoms were those of increased intracranial tension (headache, vomiting). In six of the cases the onset of the symptoms was fairly sudden and something of the nature of an ictus was observed, possibly due to neoplastic embolism.

Later Signs and Symptoms.—Correlation of the ante-mortem signs and symptoms with the post-mortem findings did not reveal anything striking, but only served to emphasise the many general difficulties encountered in the localisation of cerebral tumours and in the separation of true and false localising signs. Some workers have noted an especial difficulty in interpreting the signs in metastatic cerebral carcinomata and have attributed this to the presence of multiple tumours; of the seven cases with intracranial metastases the tumour was single in four.

Site of the Tumour.—Grant¹⁵ and Krastling and Silvan refer to the special frequency of metastases on the left side of the brain and attribute this peculiar selection to the cerebral vascular arrangement. In our series, in three cases the tumours were bilateral, in three cases the neoplasm lay on the right side, and in only one was there a single tumour in the left hemisphere.

General Condition of the Patient.—There was extreme emaciation in four cases; in three the body nutrition

was fair, and in two it was quite good when the patient came under observation, but there was a very rapid loss of weight before death.

Pyrexia.—Five of the patients showed irregular pyrexia; two cases were apyrexial and in two the temperature was raised only in the post-operative period. Moise¹¹ found pyrexia in all his cases.

Papilloedema.—Of the seven cases in which intracranial neoplasms were found, three showed papilloedema and in four the discs were normal. Globus and Selinsky¹⁷ state that papilloedema in these cases is infrequent.

Psychological Condition.—Three of the seven cerebral cases were almost normal, but in four the cerebration, coöperation, and memory were poor and depression or euphoria was present. In three cases the psychological symptoms were pronounced early in the disease and in each a frontal tumour was present. On the other hand, one of the patients, who was normal psychologically until about ten days before death, had tumours in both frontal lobes. The importance of a history of sudden onset of a psychosis in making a diagnosis of a metastatic cerebral carcinoma is emphasised, among others, by Grant, McCarthy, Crouzon, Hyde, and Curschman. The alternating periods of delusions and clarity, to which Siefert¹⁹ called attention, were not observed in our cases. The general tendency was to an increasing drowsiness and lethargy, and to a gradual increase in mental confusion and a desire to be left alone, without any marked restlessness or noisy, busy delirium. In only one patient (No. 8), who was markedly euphoric and in whom a frontal tumour was found, was there any tendency to restlessness.

Speech.—Siefert¹⁹ stated that a "peculiar disturbance of speech" was to be noted in these cases. Of our seven cases, some abnormality was observed in five. The nature of the defect seems to have been rather obscure; the descriptions in the clinical notes included slight defect, dysphonic, indistinct, husky, dysarthric. Possibly in some of the cases the abnormality was the result of intrathoracic pressure.

Recognition of a Syndrome.

Many points have been discussed in order to attempt to account for the inaccuracy of the ante-mortem diagnoses, to permit of criticism of the findings of previous investigators, and to determine whether a "cerebral-metastatic syndrome" could be established. The conclusions arrived at by various authors vary considerably. For example, Winkelman⁸ and Shelden¹⁸ state that there is no characteristic group of symptoms by which a metastatic tumour of the nervous system can be recognised. Other investigators are intermediate in their views and think that there are no definite peculiar physical signs but that there are some peculiar features, such as abnormal wasting and the sudden development of a psychosis. Globus and Selinsky¹⁷ were tempted to regard the following as characteristic of metastatic brain tumours: (a) the acute and precipitate onset of cerebral manifestations, often of a disjointed and disseminated character; (b) symptoms of intracranial pressure out of proportion to the neurological findings; (c) infrequency of papilloedema; (d) meningeal signs and radicular pain; (e) rapid decline with diffuse signs; (f) psychotic manifestations. Siefert¹⁹ gives the following picture which he believes leads to the probable diagnosis of multiple carcinomatous metastases in the central nervous system: (a) occurrence in advanced age; (b) rapid failure of health; (c) increasing apathy; (d) alternating periods of delusion and clarity; (e) peculiar speech disturbances; (f) infrequent papilloedema; (g) pain in the neck; (h) vesical disturbances; (i) weakness of the extremities and the right seventh nerve; (j) changes in the gait and tendon reflexes.

Our observations lead us to think that it is incorrect to say that there are no special features by which these cases may be recognised; on the other hand, there is not a clear-cut cerebral metastatic syndrome

characteristic of all cases whether the primary lesion is in the lung or elsewhere. Nevertheless, there are certain features which are common to the majority of cases and a typical case might be portrayed as follows: An elderly patient, with wasting—out of proportion to the extent and duration of the cerebral symptoms—early confinement to bed, pyrexia, a short history with possibly a sudden onset of a psychosis followed by a temporary recovery, radicular pain, vague chest signs or a history of a respiratory abnormality, and a rapid progression to death.

Points such as the infrequency of papilloedema, speech disturbances, vesical disturbances or multiplicity of cerebral signs do not appear to be of sufficiently distinctive value to merit inclusion. Although the features which are most frequently encountered in these cases have been combined in order to present a composite typical picture, it must be remembered that some cases, possessing only three or four of these points, may present a markedly different appearance. For example, Case 1 was a man of 37, who was apyrexial, normal psychologically, and who showed no abnormal chest signs. In any obscure cerebral lesion, it is important to bear in mind the possibility of a metastatic cerebral tumour and the necessity for a careful and complete clinical and radiological examination.

Pathology.

The views on the pathology of primary carcinoma of the lung have recently undergone considerable change. At one time it was usual to classify these tumours into: (a) columnar-celled type arising from the bronchial mucous membrane; (b) polyhedral-celled type arising from the bronchial mucous glands; and (c) squamous-celled type from the alveolar epithelium. Shaw Dunn²² has pointed out the extreme difficulty in classifying pulmonary neoplasms according to this scheme, in view of the pleomorphic nature of the cells composing the neoplasm. Duguid⁹ says: "Although there is a wide variation in the structure, even the most remotely divergent cases appear to be linked together by a series of intermediate types, which makes it difficult to see where any division in classification could be made." Shennan¹⁴ stresses the marked degree of pleomorphism of the cells seen in a great proportion of these tumours, but considers that he is able to recognise six types. In addition Barnard,¹⁰ in 1928, showed that many of the so-called mediastinal sarcomata were in reality carcinomata of pulmonary origin; they were designated by him "oat-celled" carcinomata. He considered that there were two groups of pulmonary carcinomata: this oat-celled variety and an obviously carcinomatous type in which the cell picture varied from the columnar, mucus-secreting type at one end of the scale to a squamous-celled type at the other, with intervening forms showing polygonal, spheroidal, or cubical cells. These facts are recalled because in all but one case of our series the primary tumour was situated in or near the hilum of the lung and at one time would probably have been regarded as a mediastinal sarcoma.

The tumours were firm and white in colour, and in seven of the cases were found on the right side. Evidence of bronchial obstruction—pulmonary collapse or bronchiectasis—was present in six cases. Microscopical examination emphasised the pleomorphic nature of the cells composing these tumours. The cells, roughly columnar in type, were arranged in solid trabeculae and showed a tendency to the formation of acini. Between the trabeculae were situated strands of fibrous tissue which carried the blood-vessels. A cross-section of such an arrangement represented what might be regarded as a unit, the whole picture being composed of a collection of these units. Each unit consisted of a central blood-vessel surrounded by connective tissue which was separated from an outer layer of connective tissue by a clear area; in this space, in many cases, collections of small round cells were found. Abutting on this outer layer of connective tissue was a single row of columnar cells

and beyond this again was a mosaic of cells of cuboidal or spheroidal type. The cells varied markedly in shape and size, some being oval, some columnar, and others cubical; in addition, groups of cells were irregularly clustered between the units. The cell nuclei were large and vesicular and numerous mitotic figures were seen in many of the sections (see Figs. 2 and 3).

Several of the features of the metastases have been pointed out in the descriptions of the cases, but we would call attention again to the production in three cases of cerebral or spinal symptoms from secondary deposits confined to bone and not apparently invading the nervous tissue. Globus and Selinsky have remarked on this selective action of these secondary deposits in certain cases. The "hollowed-out and oyster-shell" appearance on the inner aspect of the skull and vertebrae formed a conspicuous feature; in one case the tumour was adherent to the dura, but there was no macroscopical evidence of involvement of the pia-arachnoid. Cornwall²¹ has recently described a case where metastatic involvement of these membranes was apparent on microscopic examination, although there was no evidence macroscopically of tumour formation. Invasion of the meninges, apparent only on microscopic examination, is also referred to by Morse.²³ Winkelman and Eckel⁹ subdivided these cases according to whether the dura or pia mater was involved; the former they termed pachymeningitis carcinomatosa and the latter meningitis carcinomatosa. This meningeal invasion probably accounts for the presence of constant and severe radicular pain in some of the cases. We have already noted the strawberry-like appearance of the intracerebral tumours, their surrounding zone of hæmorrhage, and their strict macroscopic demarcation from the surrounding brain tissue. Microscopically an overgrowth of neuroglia with spider-cell formation could be demonstrated at the margin of the tumour. The microscopical appearances of the secondary deposits were similar to those of the primary pulmonary tumour. On the whole, however, the cells were larger in size and varied in shape from true columnar to oval; in many cases an alveolar arrangement could be made out. The nuclei were deeply stained and very small. Fibrous tissue varied in amount but was, generally speaking, more scantily distributed in the lung tumours.

Conclusions and Summary.

1. Nine cases of primary lung tumour with metastases giving rise to cerebro-spinal symptoms are reported, with clinical and pathological details.

2. The suggested factors in the ætiology of primary lung carcinoma are discussed; no further information is forthcoming as to the cause or the recent increase in incidence.

3. The views of previous investigators as to the existence of a cerebral metastatic syndrome, or peculiar features by which a metastatic cerebral tumour could be recognised, are criticised.

4. A composite typical picture of a metastatic cerebral carcinoma is presented.

5. The macroscopical and microscopical appearances of the lung and cerebral lesions are detailed.

6. The necessity for bearing in mind the possibility that a cerebral lesion may be a metastatic carcinoma from the lung or some other source is emphasised.

7. The difficulties in diagnosis necessitate a complete and careful examination, clinical and radiological.

We wish to express our gratitude to the physicians of the National Hospital, Queen-square, for permission to publish reports of the cases under their care, and to Dr. J. Godwin Greenfield for his ready help and kind assistance, especially in the preparation of the microphotographs.

"RUSH" INOCULATION,

WITH SPECIAL REFERENCE TO HAY-FEVER
TREATMENT.

By JOHN FREEMAN, D.M., B.Ch. Oxf.,

DIRECTOR OF THE DEPARTMENT OF CLINICAL BACTERIOLOGY,
ST. MARY'S HOSPITAL.

THE approach of the hay-fever season recalls to the mind of the immunologist the whole question of desensitisation—for it is with hay-fever that we have the greatest and longest experience of a specific sensitisation disease. Recent developments in desensitisation of hay-fever patients are most easy to explain when looked at historically.

Passive Immunisation with Serum.—In 1903 W. P. Dunbar, in Hamburg, made the first attempt to desensitise hay-fever subjects to grass pollen by passive immunisation, utilising for this purpose the sera of horses and geese.¹ That method has gradually fallen into disuse.

Leisurely Desensitisation.—In 1900 Noon and I began inoculating hay-fever subjects with a grass pollen vaccine.² We began in the off season—i.e., when there was no pollen about—say at the beginning of March; inoculations were given weekly merely because our out-patients at St. Mary's Hospital were in the habit of coming every week. After we had arrived at what we believed to be an effective dose we made little or no attempt to increase it—being influenced in this by the routine practice for therapeutic immunisation. This plan has worked fairly well, and is still perhaps the method in most general use. In view of subsequent quicker methods I have called this older method "leisurely."

Intensive Desensitisation.—Later (1924) when desensitising horse asthmatics or other animal sensitives to horse dandruff, &c., I fell into the way of inoculating these patients every day with gradually increasing doses (a 10 per cent. to a 20 per cent. increase). There was no off season with these people, and they were usually in a great hurry to go and hunt, or look after their dogs, or retrieve their cats from quarantine with the veterinary surgeon. This intensive method proved so successful, and was in some ways so convenient, that in 1926 I gave it to a number of hay-fever patients, and have used it increasingly ever since.³

"Rush" Desensitisation.—The anti-anaphylaxis method of Besredka suggested a quicker desensi-

tisation, which I have used since 1928. The injections are given every hour and a half to two hours throughout a 14-hour day. Thus a very satisfactory course can be put through in from two to four days. The patient must go into hospital or some such institution, or at any rate be in the charge of a trained nurse, and under the constant supervision of the doctor. As with the previous methods a safe initial dose is estimated by the intensity of the diagnostic reaction (see below); a very slightly sensitive person might receive, say, 100 or even 200 units of pollen; a very sensitive person—i.e., one giving a centimetre-broad wheal when pricked through a drop of pollen extract of 500 unit strength—had better receive no more than 20 or 30 units for the first dose. As with the intensive course an increase of 10 per cent. to 20 per cent. on the preceding dose is made at each re-inoculation if this can be borne by the patient without any discomfort. If there is a reaction, then the percentage increase is slowed down, or stopped, or a smaller dose is given. Because the doses are mounting in geometrical progression it only takes a few days for a dose of, say, 100 units to mount to perhaps 20,000.

The notes of a few typical cases will show the general nature of the "rush" method of desensitisation and its special application to hay-fever. My first case so desensitised was a dust asthma case (presumably mould spores), the second was a fish-sensitive, the third was a horse-asthmatic, and the fourth a hay-fever case from the batch so treated in 1929.

A Dust Asthma Case.

A. B.—In 1928 a man came into our male laboratory ward for intractable asthma. He had neither food sensitisation nor animal asthma. He was much worse in winter when he had "colds," and generally, by a process of exclusion, the case seemed to resolve itself into one of a bacterial sensitisation. At any rate the bronchial infection was an "asthmatic factor" in him; so far as we could see at first it was the most important factor; and it was one we could treat. Suitable inoculations of a bacterial vaccine—aided, as subsequent events suggest, by mere absence from his home—"cured" him and he was discharged from hospital. He came back three days later, just as bad as ever, with the story that he had relapsed on the very first evening at home. Similar treatment (but in a shorter time) again "cured" him, and he was again discharged from hospital; but he came back next day with the same story of a relapse. A few days later he left the hospital for the third time, quite well, but saying "Keep my bed warm for me, I shall probably be back to-night"; he came back in an hour or so—and just as bad as ever. Clearly we had here a locality factor in his asthma. After he had got well for the fourth time in hospital he was found to react violently to an extract of the fine dust from his house; by intradermal injections he was 3000 more sensitive than the normal man. As he had spent time enough in hospital I embarked on the "rush" method.

He got subcutaneous injections at first every 20 minutes; later on he got them every hour (except during the night),

beginning with a very weak dose (80 units) and increasing roughly by 20 per cent. at each re-inoculation. At the end of three days I got him up to a dose of 2 cubic centimetres of the strongest extract I had made—i.e., a dose of 200,000 units. He was then discharged from hospital for the fifth time, and again quite well. He got no asthma at home that night or on subsequent nights; he has had no serious attacks since then.

This quick success seemed—both to the patient and inoculator—more cogent than that of the older and more protracted treatments; and as it was clearly of general application it has since been used with success for desensitisation to animal asthmas (horse and cat), for food sensitisations (fish and egg), and particularly for hay-fever cases. I have tried it for a number of bacterial sensitisations, but have not been so successful with them. Here there is a tech-

FIG. 1.

Chart showing the rapidly increasing doses of fish vaccine given to a sensitive patient over a period of eight days, and the effect on his skin reaction to fish and to egg. +—urticaria. *—marked urticaria and headache.

nical difficulty because attempts at desensitisation influence the growth of the bacteria which are producing the toxæmia; but even here it is believed that "rush" desensitisation has a future.

A Fish-Sensitive Patient.

C. D., a boy of 7 years with bad bronchial asthma, had also a number of food sensitisations which were not only helping to keep up his asthmatic condition but were also making him an undernourished and undersized little boy because of the difficulty in feeding him. He was particularly sensitive to fish; his lips blistered on contact with this food which, if swallowed, caused vomiting and diarrhoea, general urticaria, headaches, and increase of his asthma—the usual crop of symptoms in fact. He was

*Hart, P. D'Arcy: Proc. Roy. Soc. Med. Section for Study of Diseases in Children. Jan., 1930, p. 265.

In the case described above it was probable that A. B. was sensitive to the mould spores of the locality; it was their presence in the dust which caused him to react to it, and which made an extract of the dust such an efficient antigen. Indeed, he proved slightly sensitive to a large number of stock extracts of mould cultures which I tried on his skin. (He was hardly sensitive at all to *Strom van Leeuwen's A. fumigatus* strain.) But the fact is that the mycology of such cases is too difficult for our present knowledge; for example, the inoculation department put at my disposal for two years the services of Mr. la Touche, a skilled mycologist, and the chief thing we learnt was the complexity of the business. In one case only of locality asthma we isolated, and as far as possible identified, many hundreds of different strains from various damp and mildewed houses without feeling convinced that we had got near the botanical solution of the case.

put through a "rush" inoculation using as antigen the juices expressed from cod fish—1 c.cm. of the undiluted juice being taken as a million units.

Fig. 1 shows the mounting doses, which rose from 30 units to 200,000 units in eight days. The chart also shows the effect of these doses on the skin reaction to fish and egg to which he was also sensitive; these were made and measured in Sir Thomas Lewis's way (as described later in this paper), and marks have been assigned to them according to the diameter of the wheal and of the erythema.

After the treatment he was put on to a fish diet, and given an ounce of cod-liver oil t.d.s., which he liked. Ever since then he can eat fish, and has daily doses of cod-liver oil and malt. He is much less faddy about his food, he is putting on weight, and has practically no asthma.

It should be confessed that the skin reaction to fish in this case which disappeared so beautifully under "rush" treatment returned a few weeks later, and now (five months later) is back at its old intensity. This is the general experience in such cases, but does not mean that all the dietetic advantage of the desensitisation has gone; it does suggest, however, that the patient will relapse in this respect also unless the improvement is maintained by occasional injections of a fish vaccine or by insistence on a fish dietary. Another point should be noted: C. D. was also sensitive to egg, and though, as shown on the chart, the skin reactions to this did not diminish so rapidly as the fish skin reactions, yet they became irregular and did diminish to some extent, and the

boy was found to be able to eat eggs, a feat which he could not perform before the treatment. This is apparently a non-specific immunisation comparable presumably to the effect produced by protein shock.

Horse-Asthma.

E. F., a girl of 7, was a horse-asthmatic but wanted to ride her pony, so elected to go into a nursing home to be "made a pin-cushion of." Starting with a dose of 60 units of horse dandruff vaccine she got to a dose of 2450 in four days. After this dose she had a sharp bout of urticaria, her lips swelled, and she felt "funny." The doses were stopped, and three hours later she suddenly went very pale with a fluttering heart. She had, it appeared, several times in the past had similar faint attacks, and this one, like the others, quickly passed away; but it was judged wiser to send her into the country to try the effect of her pony on her. She has ridden daily without discomfort, and she is having a dose of 2000 units every ten days or a fortnight to keep up the good effect, and this 2000 dose may perhaps be cautiously increased.

This case will serve to show the care necessary in

conducting what is after all a very strenuous method of treatment. Such treatment for the uncomplicated cases of horse-asthma seems to be consistently successful but they tend to relapse after a period of from three months to a year. However, if a maintaining dose is given every ten days or so, the condition can be kept up indefinitely. I have in this way kept going a number of such cases for three or more years; and they hunt regularly.

Hay-fever.

G. H. is a young gymnastic instructress with uncomplicated hay-fever. She had been inoculated by me in past years with pollen vaccine somewhat perfunctorily but more or less successfully. In the spring of 1920, owing to pressure of work, she had practically no preventive treatment. Early in June she arrived in a desperate state, a mental and physical wreck, and quite unable to carry on her work. She had been getting steadily worse for the last two weeks, but had tried to stick it out. She was taken into hospital and put through a "rush" course of pollen inoculations (see Fig. 2). In four days the dose had risen from 100 units to 17,000 units. The patient then left hospital to catch up the arrears of work—after which she went and "rolled in a hayfield without being able to get a sneeze out of it." She was cured—for that year at any rate.

Advantages of the "Rush" Method.

The advantages of the "rush" method are:—

(1) A saving of time. Not only does the patient become desensitised in a shorter space but there is a saving of tiresome details, such as remembering to go for and getting the dose, and perhaps afterwards waiting for possible reactions. All this amounts to an unconscionable dislocation of affairs if repeated day by day.

(2) Since the business can be put through in a few days a convenient time may be waited for; one may even wait till the patient is in real distress from the disease—always a good time for getting a patient to do what he is told.

(3) As the patient is under observation all the time, a competent nurse can judge the onset and extent of any reaction more exactly, and can adopt counter-measures—e.g., repeated minute doses of adrenalin—more easily than is possible when the patient is at large.

(4) The doses can be adapted to the particular needs of each patient more exactly. Patients vary in their capacities—so may these particular antigens. Pollen vaccine is not precisely the same from year to year; it is difficult to standardise a vaccine of cat scurf. To put this another way, with "rush" desensitisation the exact initial dose does not matter so very much. At the worst one only wastes a day before getting effects.

In choosing a system of desensitisation one need not, of course, adhere rigidly to the leisurely, intensive, or "rush" methods; an intelligent blend may serve one's turn better. Thus in the early spring doses may be put in when occasion offers; if by mid-May there have been too few the pace may be quickened up even to once a day; and if unhappily grass meadows demonstrate in June that this has been insufficient, then a short "rush" treatment in a nursing home should clinch the matter.

Whatever system or combination of systems of inoculation is employed, it is necessary to make sure that the sensitisation is to one single foreign substance; or if it is multiple, that the other sensitisation will not interfere with success of treatment—e.g., it is courting failure to desensitise a hay-fever subject with grass pollen only, if the patient is sensitive to, say, a bacterial infection or to mould spores in his house.

Again it is just as necessary to make certain of the specific diagnosis before beginning treatment. For this purpose any of the established methods may be employed: (1) for eye reactions, carefully graded dilutions of the extract may be dropped into the conjunctival sacs. (2) for dermal reactions these same extracts are rubbed into scratches on the skin. (3) for the intradermal reactions a measured quantity

of a known extract is injected into the thickness of the skin. (1) and (3) are the most delicate, but, on the other hand, greater care has to be taken not to test too severely. A convenient method is that

FIG. 3.

Record of a typical wheal and the margin of an erythema by a tracing on a microscope slide.

described by Sir Thomas Lewis* in using histamine on the skin: you place a drop of the extract on the forearm or thigh of the patient and then prick through it lightly (not more than a millimetre) into the thickness of the skin with any sharp needle; after this

* Lewis and Grant: Heart, xl, 209.

the drop can be wiped off the skin. A control drop of water or normal saline should be pricked through on a neighbouring site—and if the same needle is used the control prick had better be done first. In a positive reaction the resulting wheal or erythema will be observable in 7 minutes or at its best in 10 or 12. The reaction can be recorded by placing a microscope slide over the area and inking in the prick, the margin of the wheal, and the margin of the erythema (see Fig. 3).

By this method a moderately sensitive hay-fever subject will give a just recognisable reaction if a 500 unit per cubic centimetre extract is employed, and a considerably larger reaction with, say, the 5000 unit extract. If a supposed hay-fever subject does not give an easily recognisable reaction with the 5000 unit extract it is doubtful if the symptoms complained of can be due to hay-fever, and desensitisation will not help him.

Conclusion.

The "rush" method of desensitisation offers many advantages when used either alone or in combination with other systems. To get successful and safe results, however, it is just as necessary as ever to be cautious.

Clinical and Laboratory Notes.

TWO UNUSUAL CASES OF CALCULI IN THE URINARY TRACT TREATED BY OPERATION.

By LOUISA MARTINDALE, M.D., B.S. LOND.,
SENIOR NON, SURGEON, NEW SUSSEX HOSPITAL, BRIGHTON.

THE two cases here described are both unusual and interesting.

Vesical Calculi Treated by Suprapubic Lithotomy.

The first patient, an unmarried woman of 57 years, sent to me by Dr. Helen Scatliff and Dr. Rodie Parkhurst, was admitted into the New Sussex Hospital on Jan. 4th, 1928. For three years she had had difficulty and pain on micturition, only passing very small quantities at a time; there was no history of haematuria. For the last six weeks the pain had

felt anteriorly per vaginam. The urine was very offensive, thick, and alkaline, with much pus and mucus, a specific gravity of 1020, and a slight trace of albumin. Blood was present but no sugar.

Except for varicose ulcers of both legs since the age of 16 the patient had had no illnesses. The menopause had occurred ten years earlier. The family history was apparently healthy.

On Jan. 5th, 1928, the patient was cystoscoped. The bladder would only retain four ounces of weak boric solution. The end of the catheter was felt to impinge upon a hard object inside the urethral orifice. On introducing the cystoscope it was impossible to get a view of the bladder mucous membrane, but a large foreign body could be felt, and the sharp shadow seen somewhat resembled two edges of wire. Suprapubic lithotomy was therefore performed under general anaesthesia on Jan. 7th. Twelve ounces of boric lotion were introduced into the bladder. The patient was then placed in the Trendelenburg position, a median suprapubic incision about two inches long was made through the abdominal wall, and the bladder was exposed below the peritoneal reflection. A sound was introduced into the bladder through the urethra and with great difficulty identified by the finger through the abdominal incision. The bladder was then opened. A large hard object was felt inside the bladder, seized with forceps, and brought out. This proved to be a large, symmetrical, pyramidal calculus. Another calculus of exactly similar shape, size, consistency, and appearance was found in the bladder and similarly delivered. No further stones were found. A large drainage-tube was inserted into the bladder, and the bladder and abdominal walls were closed in the usual way.

Recovery was slow. For the first four days after operation the pulse-rate was about 120; the pyrexia was moderate and lasted 11 days. On the second day a self-retaining catheter was inserted through the urethra; bladder washouts were given daily. The haematuria and pyuria gradually cleared up, the wound healed, and the patient was able to leave hospital by March 27th. She returned to my follow-up clinic six months and one year after in excellent health.

Examination of calculi.—The two calculi (Fig. 1) are of similar shape, size, and consistency. Each is pyramidal, having four surfaces, each of which is 4 cm. long, whitish-grey in colour, and on section showing concentric laminated surfaces. X ray examination showed no differentiation of structure, and no central foreign body (Dr. E. M. Magill). "Each stone weighs 40.5 g. (the two together approximately

FIG. 1 (Case 1).

Two symmetrical pyramidal vesical calculi (natural size).

been considerably worse, especially at night, so that insomnia and "feverish attacks" had been marked features in the case. The frequency had also increased during the last few weeks until, on admission, the patient was passing urine as often as every ten minutes. She was thin and pale and looked ill. Her appetite was very poor. She showed an evening temperature of 99° F. Nothing abnormal was found in the heart, lungs, or abdomen, but a hard, tender mass was

FIG. 2 (Case 2).

Ureteral calculus
(natural size).

4 oz.), and is composed of calcium phosphate with small quantities of calcium carbonate and organic matter" (Dr. Cavendish Fletcher).

Ureteric Calculus Treated by Ureterolithotomy and Later Nephrectomy.

The second patient, a lady aged 34, was brought to me by Dr. Winifred Buckley on Jan. 31st, 1927, complaining of pain in the left groin for the last three years—coming on in "attacks," worse on putting her feet to the ground, and lasting on and off for five to six weeks at a time. She also described attacks of pain over the bladder, and great pain during the act of micturition, with a feeling of soreness after; there was never any frequency, and the quantity of urine passed was about one pint in 24 hours. There had been no previous illnesses and there was no family

history of tuberculosis. Menstruation was irregular, with some dysmenorrhoea.

The patient was well developed and healthy looking, with a good colour. There was a slight definite tenderness in the left iliac region. The lungs, heart, uterus, and ovaries were normal, and nothing abnormal was detected by rectal examination. The temperature was 98° F. and the pulse-rate 82. The urine was of a pale, clear, yellow colour, its specific gravity was 1005, and its reaction neutral. No albumin, sugar, blood, or pus were found.

On Feb. 11th I performed a cystoscopy under scopolamine and morphine. The right ureteral catheter passed up to the right renal pelvis with ease and secreted freely. The left opaque catheter stopped 7 cm. beyond the vesical ureteral orifice and there was no secretion. Skiagrams were taken by Dr. Magill on two different occasions. These showed a shadow the size of a date-stone in the pelvic portion of the left ureter, about 7 cm. from the ureteral bladder orifice. The left kidney was enlarged, chiefly in the transverse direction, the lower pole reaching as low as the lower border of the third lumbar vertebra. Within its area seven small shadows were seen, suggestive of renal calculi.

On Feb. 16th I operated under general anaesthesia. The patient was first put in the lithotomy position and the left ureteral catheter was passed up to the stone and left in situ. She was then put in the Trendelenburg position and a Gibson's incision made, one inch above and parallel with Poupart's ligament, and continued up to the anterior superior iliac spine and beyond it. It was then deepened to divide the anterior sheath of rectus and continued between the fibres of the external oblique and internal oblique, and the peritoneum was carefully pushed inwards to get at the calculus extraperitoneally. The ureter was exposed

and opened one inch above the stone, which was "milked" upwards and extracted. A fine rubber catheter was passed up into the kidney, which was much enlarged, and about 3 oz. of urine drained off. A probe was then passed down into the bladder, to be sure that there was no further obstruction. The opening in the ureter was closed with one layer of interrupted fine catgut stitches, followed by an uninterrupted catgut suture embedding the first layer, and the abdominal wound was closed in the usual way. Drainage was provided by means of a strip of dental rubber.

The ureteric stone measured 1.7 by 1 cm. It was yellowish-brown in colour, covered by crystals, and consisted of calcium oxalate (Fig. 2).

Convalescence was long and tedious and complicated by pyrexia starting on the second day. For three weeks the evening temperature varied between 100.6° and 101.8° F. and the pulse-rate between 98 and 120. On Feb. 24th a blood count by Dr. G. L. Eastes showed 21,000 white corpuscles, composed of: small mononuclears, 9.4 per cent.; large mononuclears, 7 per cent.; polymorphonuclears, 83 per cent.; and mast cells, 0.8 per cent. The red discs appeared normal, and there were no abnormal types of cell. Dr. Eastes, however, reported that "considering the extensive operation and the leucocytic infiltration incidental to repair of such a large area," he would not "say there was necessarily pus." On March 11th the leucocyte count was: 15,600 per c.mm., and the differential count showed: polymorphonuclear leucocytes, 71 per cent.; lymphocytes, 28 per cent.; eosinophils, 0.5 per cent.; basophils, 0.5 per cent.

The patient, however, made steady though slow progress and was able to leave the home by the end of March, free from all symptoms. She returned to her work in the course of the next six weeks.

On Dec. 13th she returned to me, saying she had been well up to the beginning of the month, except for occasional backache. Since then, however, she had had three attacks of bad pain in the back and left groin. They were accompanied by a slight rise of temperature and insomnia, and she feared another ureteric stone. On examination I found the left kidney enlarged and tender. The patient, however, looked well, and was able to work. Dr. Magill made an X ray examination and diagnosed enlargement of the left kidney, which still contained small shadows suggestive of renal calculi.

I therefore performed another cystoscopy on Dec. 16th.

The right ureteric catheter passed with ease and secretion was rapid. The left ureteric catheter passed 4 cm. only, and although I could see some secretion from the left ureteric orifice round the catheter, I could get no flow of urine through the catheter itself. Urine from the right kidney was amphoteric and showed a minute trace of albumin, but was quite free from pus, and no bacteria were found in stained smears. Culture showed it to be sterile. Urine from the bladder was amphoteric, and quite free from albumin and pus, and no bacteria were found either in smears or culture.

On Jan. 15th, 1928, as the pain was occurring daily and the patient complained of vomiting every morning and insomnia, I decided to perform a nephrectomy. Under general anaesthesia I made a lumbar incision, which had to be prolonged in order to remove the much enlarged adherent kidney. At the same time I dissected out the ureter, removing it to one inch below the old fibrosed stricture at the site of the original ureteric stone.

The kidney (Fig. 3) was four times its natural size, contained 8 oz. of urine, and was markedly lobulated, and the pelvis was dilated and sacculated (hydronephrosis). The kidney tissue was compressed and atrophic. A section was taken of the kidney substance and the features were those of a subacute or chronic inflammatory reaction. There was an infiltration of leucocytes and plasma cells and the characteristic changes of a chronic interstitial nephritis. Much of the functional tissue had been destroyed.

The urine was faintly alkaline, contained a small amount of albumin, and yielded a small red deposit which consisted of blood with some transitional epithelial cells. No pus and no bacteria were seen in the Gram-stained smear. The cultures were all sterile (Dr. Eastes).

The convalescence was again a stormy one. Slight pyrexia started on the second day. From the seventh to the eleventh day there was a swinging temperature from 97° F. in the early morning to 103° or 104° F. in the evening. On Jan. 31st the leucocyte count was 11,800 per c.mm. On Feb. 1st the temperature became normal. On the 3rd, however, both pus and albumin were present in the urine, and on Feb. 14th a catheter specimen showed an acid urine with a distinct trace of albumin and a fair quantity of pus with many bacilli, which grew well in culture as a *Bacillus coli*. With treatment, however, this quickly disappeared, and the patient was able to leave the home on Feb. 20th.

On Sept. 10th, 1928, I found the right kidney enlarged and the urine normal. The patient was well and feeling better than she had done for years and able to enjoy her

work. Her subsequent history has been very satisfactory except for an acute appendicitis, for which I performed an appendectomy on Nov. 17th, 1929.

The chief points of interest in Case 1 appear to be:

1. The unusual occurrence of a bladder stone in a woman. Only 5 of the 371 cases operated upon in St. Peter's Hospital during the decade under review were females, and in at least two of these the stone was formed round a foreign body. (See Swift Joly's recent work on "Stone," 1929.) Sir Peter Freyer operated upon 31 females out of a total of 1623 patients. E. Keyes, 1928, states that he has operated upon over 70 men and one woman, and his father upon 250 men and three women. I have operated on three women for vesical calculi.

2. The unusual size and the extraordinary resemblance of the two calculi.

3. The recovery and subsequent good health of the patient, for the mortality of operation upon large bladder stones is extremely high. These cases invariably have a gravely impaired renal function through chronic renal infection (E. Keyes, "Urology," 1928).

The chief points of interest in Case 2 are:

1. The marked leucocytosis and pyrexia following the removal of the ureteral stone, considering the non-infected condition of the kidney as found in the subsequent nephrectomy.

2. The fibrotic stricture either at the site of the incision into the ureter or at the site of the stone as it lay in the ureter one inch below the incision, necessitating a nephrectomy later.

Here it is difficult to decide whether it was the impaired function of the hydronephrotic kidney (already caused by the ureteral calculus) which led to fibrosis and stricture, or whether the double row of stitches was the cause. In view of the condition of the kidney found at the second operation, the former seems the more probable explanation.

INJURIES OF THE FASCIAL INSERTIONS OF MUSCLES.

By B. S. NAT, M.B. ST. AND., F.R.C.S. ENG.,
CAPTAIN, INDIAN MEDICAL SERVICE.

THE following two cases that came under my care in 1926-27 while serving at Razmak on the frontier illustrate the clinical importance of these injuries, hitherto not well recognised, in healthy young adults.

CASE 1.—A Gurkha sepoy complained of weakness and a sense of insecurity in his left knee. He traced it to a strenuous game of football at Dehradun 18 months ago. While kicking he felt something give way in his knee with a clicking noise followed by pain. He noticed that he could not extend the knee on account of pain and the joint soon became swollen. With rest followed by massage his knee recovered in about ten days. He has never had any repetition of this kind of attack but has suffered from pain and weakness in the limb which became worse after marching. As he had been labelled malingering at his previous station he did not report sick till his regiment came to Razmak.

Examination.—There was no fluid in the knee. Quadriceps well developed. No localised tenderness at any point. The knee could be extended fully without any pain. On the outside of the knee in front of the tendon of the biceps a band (the iliotibial of fascia lata) could be felt slipping forwards and backwards over the outer aspect of the lateral femoral condyle. When the band was prevented from its abnormal to and fro movement by pressing it against the femoral condyle the clicking noise accompanying extension disappeared.

Diagnosis.—The absence of any fluid in the synovial cavity of the knee suggested an extrasynovial cause for the complaint and its accompanying sound. On careful examination the abnormal to and fro movement of the iliotibial band was noticed. The case was, therefore, diagnosed a tear of the deep fascia which fills up the triangular interval between the tendon of the biceps femoris and the iliotibial band.

Operation.—Under novocain block an incision was made over the triangular interval above referred to and an inverted V-shaped tear was seen in the deep fascia. The

edges of the gap were rawed and fastened together by strips of fascia from each edge reinforced by a few catgut stitches. The knee was kept at rest for three weeks with quadriceps massage after ten days. Patient was gradually allowed to bring his knee into full use as a soldier's knee. He was completely cured of all his trouble and was alright for the six months for which he was under my observation.

Remarks.—The history was suggestive of a mild contusion of the semilunar cartilages. There is no doubt that the synovial membrane was injured in the accident, but this intra-articular part was evidently completely recovered from, while the extra-articular lesion was the cause of his later symptom.

CASE 2.—Private X (Rifle) traced his symptoms to a mile race in which he took part more than two years before I saw him. There was no definite history like the first case. The patient complained of a liability while running to a clicking noise accompanied by uneasiness in his left hip which was now more easily fatigued.

Examination.—Briefly there was nothing in his hip-joint, but like the first case the iliotibial band was felt slipping with an abnormal to and fro movement over the great trochanter when the hip was semiflexed and alternately rotated inwards and outwards.

Diagnosis.—The case was diagnosed on the strength of the last case as a rupture of the gluteus maximus insertion into the fascia lata.

Operation.—A tear was found at the time of the operation but it was not so definite as in the first case. It was found that ordinary stitches were not enough to hold back the iliotibial band in rotation of the hip. Deep mattress sutures with No. 4 catgut however succeeded in doing so. Patient was allowed to get up with the same after-treatment. His symptoms were relieved for the period (three months) for which he was under my observation. I am, however, not so very optimistic about the ultimate result in this case.

Commentary.

Fascial attachments and muscular insertions into deep fascia may thus be of considerable surgical importance, on which perhaps some light may be thrown by considering the natural purpose of a partial muscular insertion in fascia. These fascial insertions of muscles are less marked in human beings than in monkeys, in which they may be useful in giving the animal an initial mechanical advantage for a quick start from the stationary position—obviously a more necessary equipment for the monkey in its struggle for existence than for human beings. A taut fascia, so to speak, keeps the car in gear for a ready start and hence the necessity for muscles that are inserted into the fascia. In the second case the patient lost speed on account of the tear noted at the operation; I cannot say if he has recovered any of it since. This case is comparable to the snapping hip (*hanche a ressort*) of some writers. Thomson and Miles (Manual of Surgery) describe this injury thus: "The condition was formerly described as a voluntary dislocation of the hip; it is now believed to be due to a cord-like band of tissue slipping backwards and forwards over the trochanter. The band is usually derived from the fascia lata, sometimes reinforced by the anterior fibres of the gluteus maximus, sometimes by the tensor fasciae femoris." It is more accurate to describe the injury (for this condition is the result of an injury) as a rupture of the gluteus maximus insertion into the fascia lata. The first type of case, so far as I can make out, has never been recorded.

LEEDS INFIRMARY.—Last year the expenditure was £104,789, being £10,680 less than the average of the last three years, and the accumulated deficit has been reduced to £63,000. Of the 1181 motor accident patients, 544 were admitted; they occupied beds for 6500 days and cost £1265, of which only £245 was repaid. An asthma clinic was opened during the year.

ROYAL PORTSMOUTH HOSPITAL.—There was great pressure of surgical work last year, 2575 operations having been performed. The work of the theatre has nearly reached its limit, but the new theatre, which is approaching completion promises, according to the annual report, to be second to none among the hospitals of the provinces. It is hoped that shortly medical and surgical beds may be separated. The average weekly cost of each in-patient was £2 4s. 6d.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF EPIDEMIOLOGY AND STATE MEDICINE.

At a meeting of this Section held on March 28th Lieut.-Colonel F. E. FREMANTLE, the President, took the chair, and Dr. WILLIAM FLETCHER opened a discussion on

TYPHUS-LIKE FEVERS OF UNKNOWN ÆTIOLOGY,

with special reference to the Malay States. He remarked that the League of Nations, in their Epidemiological Report for December, had stated that typhus was the least interesting of all the infectious epidemic diseases, implying that everything was known about it and that it did not interest the research student. It was hard to believe that such an opinion could be entertained by anyone who had seriously investigated the many unsolved problems of the disease. He began by describing his own experience of the exanthem which in Malaya was called tropical typhus. Some six years ago he had seen a Sikh woman and her daughter, aged 11; they had been in hospital for about a fortnight and were lying in a drowsy typhoid state. He had examined the blood with his stock culture of *B. proteus* X 19; this strain had been thought at the time to be an ordinary culture of X 19, but was now known as the "K" or Kingsbury strain. The blood of the mother had agglutinated this strain in a dilution of 1 in 3000, and the daughter's blood at 1 in 1600. He had reported, to the great horror of the medical officer of health, that the patients were suffering from typhus fever. The diagnosis had been vehemently questioned, because it had been supposed that there was no typhus in the country, the patients had lived on an isolated farm, they had been well on the way to convalescence after the 17th and 18th days respectively, and the disease had not spread to the other inmates of the rather overcrowded general ward. Other cases of the same kind had subsequently occurred in various parts of the country. The symptoms were those of mild typhus and the rash in Europeans was like the rash of typhus, but in the dark-skinned Asiatics was difficult to detect. The agglutination with the K strain became positive towards the end of the second week of illness, reached its highest titre at the beginning of the fourth week, and then declined. The cases were always sporadic, and had no connexion with one another except where a common source of infection was suggested. The disease never spread in hospital. Body lice were not found, and there was plenty of evidence that the disease was not carried by head lice. It did not occur among town-dwellers, but affected those whose work took them into waste land covered with scrub and long coarse grass.

Serological Distinctions: Classification.

A number of cultures of *B. proteus* X 19 had been found, to the surprise of the workers, to differ antigenically and in their biological reactions from the K strain; moreover, they had not been agglutinated by the blood of these patients. The disease was clearly not typhus, because it did not spread from case to case and because the Weil-Felix reaction was negative with the ordinary strain of X 19. Nevertheless it must be closely related to typhus because of its positive agglutination with a strain of *B. proteus*. Cases had later begun to appear which gave a positive Weil-Felix reaction with normal X 19. Clinically they differed little from the others, but they all occurred in town-folk. Shopkeepers were so liable to the disease that it had been given the name of tropical shop-typhus, in order to distinguish

it from the other form, which was called tropical scrub-typhus.

Scrub-typhus had a patchy distribution and clung to certain estates and pastures; on plantations it was more or less limited to the older parts. The chief sufferers were the coolies who worked in close contact with the palm-trees. When palms were five years old these workmen had to hack off the lower fronds and dead flowers, which seemed to be the source of the infection. The resemblance of scrub-typhus, both in its epidemiology and in its serology, to Japanese river fever (tsutsugamushi disease) made it possible that the vector was a trombicula and that the reservoir of the virus was probably a rat. The ears of rats caught on the estate, where many of the observations were made, usually carried *Trombicula deliensis*.

Tropical shop-typhus was also a sporadic disease which did not spread; although it was not louse-borne its occurrence in towns and its positive Weil-Felix reaction showed that it was more nearly related to typhus exanthematicus than was scrub-typhus. It was probably identical with the endemic typhus of South Australia and of the United States (Brill's disease). There was little evidence to incriminate any particular arthropod.

Typhus-like diseases similar to those of Malaya occurred in many parts of the world. The spotted fever of the Rocky Mountains and the Japanese river fever were closely related to typhus exanthematicus. J. W. D. Megaw had classified all these diseases according to their vectors into the four groups of louse-typhus, mite-typhus, tick-typhus, and typhus-like diseases of which the vector was unknown. The Malayan forms fell into the fourth category. Diseases of this last class occurred all over the warmer parts of the world and, where there was seasonal variation, occurred chiefly during the hotter months. It must not be supposed that they were all different diseases, but they could not all be one disease. At present they fell into the two main groups of urban and rural, but as their vectors were discovered they would probably be transferred one by one into the first three classes of Megaw. If they occurred in England at all, they must be rare and very difficult to diagnose from true exanthematic typhus.

The PRESIDENT pointed out the necessity of facing the fact that the diseases Dr. Fletcher had described did not fit into the recognised text-book knowledge. The old ideas, valuable in their time, were giving place to more human conceptions. He recalled an epidemic in the Boro, in his early days of a disease which had probably been identical with one of the newly discovered syndromes.

Nomenclature.

Dr. E. W. GOODALL, as did nearly all subsequent speakers, repudiated the statement in the League of Nations' report that no one was interested in typhus. He pleaded for nomenclature by prominent symptoms and objected to the terms "scrub-" and "shop-" typhus. If these conditions were not typhus, they should have names describing what they were like. Mild forms of classical typhus occurred both sporadically and in epidemics. He suggested for all these typhus-like diseases the name "typhus minor." The Marseilles disease, however, had been shown by workers on the spot not to be typhus, at least clinically, nor was the Japanese river fever typhus, judging from Dr. R. G. Archibald's account of it (The Practice of Medicine in the Tropics).

Dr. Fletcher had distinguished his tropical forms from classical typhus by their mildness, non-infectivity, different seasonal incidence, different social incidence, their propagation by some means other than lice, and their serological reactions. Dr. Goodall adduced variola minor as an instance of a mild form of a well-known disease; moreover, the epidemic typhus of Australia, one of the diseases which Dr. Fletcher had enumerated, had recently shown a 10 per cent. death-rate, one quite up to the standard of true typhus. True typhus had occurred in this country without spread over and over again. Scarlatina

was most prevalent in this country in the early winter and in the United States in the early spring, but the disease was the same in both countries. Typhus, according to Orliehot, had occurred among the higher as well as the lower classes, and Dr. Goodall had seen a small epidemic among well-to-do persons in Stepney whose house had been exceptionally clean. He had observed cases in which he doubted very much whether the disease had been conveyed by insects at all. Finally, serological anomalies might occur in homologous diseases.

The Causal Organism.

Sir ANDREW BALFOUR recalled a case occurring in a British soldier in Khartoum, of what had possibly been one of the forms described by Dr. Fletcher; it had been different from typhus but had answered very closely to the description given by A. Conor and A. Bruch of what was now supposed to be the same as the Mediterranean *fièvre exanthématique*. It had been mild and had had the peculiar clinical feature that the rash had occurred on the palms and soles as well as, slightly, on the face. The best example of a disease carried by a number of vectors was the tularæmia of rabbits, which might be conveyed by ticks, fleas, and other arthropods and which had been found in Japan, Soviet Russia, and other places besides America. Its wider incidence, like that of typhus, had remained unrecognised until it had been pointed out by an especially shrewd observer. While agreeing with Dr. Goodall that topographical nomenclature might be misleading, Sir Andrew held that scrub-fever and shop-fever were useful terms until more was known about these forms. The chief difficulty was lack of knowledge of the ætiology. He had himself always been doubtful whether rickettsia was the active organism of typhus. The current number of the *Marseilles Médicale* had contained a paper on a case of Mediterranean typhus where dog ticks had been suspected as the vector. He welcomed the investigations which Dr. A. Anigstein, of Warsaw, was making in Malaya for the Colonial Office.

Dr. J. A. ARKWRIGHT testified to the value of the study of the rare forms of typhus for the elucidation of the whole question. Recent workers in the United States had found rickettsia to be commonly present in guinea-pigs and rats inoculated with European and Mexican typhus and the sporadic typhus of the South-Eastern States; the organism had been successfully transplanted into *Pediculus corporis*. This result would suggest that rickettsia was really the ætiological organism of typhus. Cross-immunity experiments in rats seemed to have established the identity of the sporadic typhus of the United States with European typhus, and the blood of sporadic cases had been passed through lice. If *Pediculus capitis* could convey typhus, the whole course of transmission would be different. The apparent absence of lice on a patient was not conclusive, as a single louse could infect.

Prof. J. C. G. LEDINGHAM saw in the results with the Kingsbury strain a promise of further enlightenment on the bacteriology of the new forms. Dr. Goodall's objection to the nomenclature did not seem to him important. The observation of small clinical differences would not help much, and progress must be along bacteriological lines. When progress had been made, correct nomenclature would follow.

Serological Tests.

Dr. A. FELIX described Dr. Fletcher's work as one of the most important advances made in the study of typhus during recent years. He had fully confirmed Dr. Fletcher's results by serological tests. The K strain undoubtedly played the same rôle in the rural typhus as *B. proteus* X 19 played in the urban and classical forms. Two strains of *B. proteus* had been used from the earliest days of the serological diagnosis of typhus, and antigenic analysis had shown that the relationship of the K strain to the known types was similar to that which existed between

the two early types. Failure to obtain cross-immunity between a typhus-like disease and true typhus might be due to antigenic factors known in other bacterial species, and could not by itself support a distinction.

Sir WILLIAM HAMER said that in epidemiology the question always arose of what the orthodox disease was, and epidemic diseases unfortunately did not behave in a very precise and orthodox manner. He had been struck years ago by the difficulty of distinguishing in some cases between diphtheria and scarlet fever, and had learnt from Dr. Goodall that there was no such thing even as an orthodox measles rash. It was necessary to take account of all the bacteriological and clinical evidence, the various facts of meteorology, and the incidence in scrub or shop, and then to return to the epidemiology of the disease. Even before the middle of the last century writers had had very definite ideas about the epidemiology of these comatose fevers, and Sydenham had grouped them on either side of the big influenzas. Typhus fever, whether in Dr. Fletcher's cases, in those studied by Dr. Goodall in Poland, or in those observed after the big influenza epidemics of the 'nineties, had certain epidemiological characters that were world-wide and had extended over centuries of time. These characters ought to be weighed together with all the other evidence.

Dr. J. D. ROLLESTON referred to the valuable work done in Germany, which had established that typhus was really a disease of the small arteries, and asked Dr. Fletcher whether the typhus nodules were found in his cases. He criticised Dr. Fletcher's suggestion that exanthematic typhus might be a comparatively modern disease. Typhus was a disease of human misery, associated with war and famine, and he thought it very probable that the Athenian pestilence described by Thucydides had been typhus. He asked whether any work had been done on prophylaxis with the serum of convalescents. A paper had recently been published by Pecari which probably threw light on the Italian *febbre eruttiva*; the author had said that it existed in Rome, and it therefore appeared to be an urban form of the disease.

Reply.

Dr. FLETCHER, in reply, said that Brill had decided shortly before his death that his disease (endemic typhus of America) was not typhus. Hundreds of cases of the kind he had described occurred without spread in different parts of the world and epidemiologically were not typhus. Moreover, the public would not have them called typhus. Dr. Goodall had said that the Mediterranean disease was not typhus, but there was a disease at Toulon which occurred on the ships and in the streets, which gave a positive Weil-Felix reaction, and which was different from the Marseilles type. He had classed the particular Marseilles epidemic he had referred to with the Japanese river fever because the symptoms were very much the same and there were similar changes in the small blood-vessels and agglutination, though only in a low degree, with the K strain. Typhus inoculation in guinea-pigs conferred slight immunity against Rocky Mountain fever, and the positive Weil-Felix reaction in Rocky Mountain fever had justified Megaw in classifying it with typhus. The names he gave to these diseases were simply provisional. In New York and Australia Brill's disease was not notifiable and was not treated as typhus. Dr. Anigstein would probably publish his work shortly. Cross-immunity did not mean that the virus causing two diseases was necessarily the same; he instanced variola and vaccinia. He did not think that head lice were concerned, because their presence or absence seemed to make no difference to the spread. He agreed that the epidemiological aspect was the most important. He had not gathered that the disease described by Pecari had actually occurred in a town. No attempt had yet been made to immunise with convalescent serum. Such histological material as he had seen resembled that of typhus.

THE DRAMATIC IN SURGERY.

By GORDON GORDON-TAYLOR, O.B.E., M.A., F.R.C.S., Surgeon to the Middlesex Hospital. Bristol: John Wright and Sons, Ltd. 1930. Pp. 88. 12s. 6d.

THIS attractive little book will afford an hour or two's entertainment to the practising surgeon, with some profit. It comprises the substance of an address delivered before the Manchester Surgical Society. Some almost incredible exploits by the author and other surgeons are recounted, which will fill the reader with astonishment, but their memory will encourage him in future times of difficulty and doubt. One lesson stands out emphatically—that success in cancer surgery comes only to him who dares. Many incidents are related which are dramatic or curious or even humorous mainly from the circumstances or surroundings in which they have occurred, as for example the rupture of a hydrocele when its possessor, a Scotchman, stooped to pick up a sixpence lying in the Charing Cross-road. The book must be read to be appreciated. It will be laid down with a feeling of regret that a gifted author of such varied and ripe experience does not more often contribute to surgical literature. The illustrations are many and beautifully executed.

THE BLOOD PICTURE AND ITS CLINICAL SIGNIFICANCE.

Seventh and eighth revised editions. By Prof. Dr. VICTOR SCHILLING, Physician-in-Chief, the First Medical University Clinic, Charité, Berlin. Translated and edited by R. B. H. GRADWOHL, M.D., Director of the Pasteur Institute of St. Louis. London: Henry Kimpton. 1929. Pp. 408. 42s.

THIS book was first published in Germany in 1912. Its eighth edition, which has been translated, is not a very impressive production. The main theme deals with the author's modification of the Arnehl system in determining the response to infection, but it is noteworthy that the two writers appear to be on terms of lively disagreement. There are four parts, the first dealing with technique. A particular method of making blood smears is given, with many methods of always made to show the degree of polychromasia, proportion of eosinophils and the presence of parasites. The hæmoglobin must be estimated, but the total red and white counts are only done when it looks necessary; otherwise the leucocytes are estimated from the smear. The usual special examinations—e.g., fragility, platelets, &c.—are described, with the additions of the sedimentation-rate and gutta-diaphot. The latter device does not sound attractive; it is admitted that its use is still mainly in the experimental stage, and the insertion of a description of it in this book savours of advertisement. The notes on blood transfusion are poor—for example, an enema of blood is suggested for small children.

Part II., called the theory, morphology, and division of the blood picture, first describes the red cells and the anemias which are classified according to the degree of "shift to the left," normoblastic, megaloblastic, and so forth, either purely regenerative—i.e., with normal young cells—or with some degenerative tendency as well. The classification is not always very fortunate—e.g., in severe aplastic anemia with little or no shift. The blood-platelets are discussed with the red cells from which the author considers they are derived. A longer section is devoted to the leucocytes, the determination of the response to infection being the main *raison d'être* of the book. The "hæmogram," or blood picture, includes normally an estimation or count of the total leucocytes, an examination of the thick drop, and the differential count. The latter is of the usual type, apart from the neutrophils which are divided into four groups: (1) segmented cells, (2) "stabs," (3) juvenile cells, (4) myelocytes. The "stabs" or "staff" cells have nuclei in the form of bent rods

and serve as an index of the degenerative tendency present, while the appearance of juvenile forms or of myelocytes shows the degree of regeneration activity. Even if one assumes that the different types can be accurately differentiated, it is clear that a very high standard of technique and judgment would be necessary in any establishment where large numbers of routine blood counts are made. The importance of the eosinophils in infection is very rightly stressed, and the interdependence between the different types of leucocytes is suggested. The discussion on the leukemias is comparatively short, and it is curious that the author should stress the use of the oxydase test, since he admits that it may be negative in the myeloblast. The blood in the child is discussed in a separate section.

Part III., on the clinical use of the blood picture, includes the changes in specific diseases, and Part IV. is devoted to 100 examples of actual cases. The cases of tuberculosis ought best to show the use of the hæmogram, but unfortunately the prognosis is not always confirmed by any subsequent history.

In general the book is far from convincing, and is written with little critical sense. The translation is too liberal, the terminology being flowery and the meaning often obscure. Four well-executed coloured plates are included and the index is very full; a large bibliography refers almost exclusively to German publications.

BIOLOGIE UND PATHOLOGIE DES WEIBES.

Ein Handbuch der Frauenheilkunde und Geburtshilfe. Lieferung 46, VIII. Band, 3 Teil. *Die Beeinflussung der Geburt durch den spontanen vorzeitigen Blasensprung.* Von Priv.-Doz. Dr. E. FREY (Zürich). Berlin: Urban and Schwarzenberg. 1929. Pp. 1903-2072. With 6 coloured plates. M.10.

IN this subsection of Halban and Seitz's well-known work Dr. E. Frey, of Zürich, deals very comprehensively with the subject of premature rupture of the membranes, discussing its causation and influence on labour and the puerperium in normal and in contracted pelves. For purposes of comparison standard tables have been constructed from records of 200 cases of normal labour and the puerperium in primipare and a like number in multipare. Such a detailed study has been rendered possible by the fact that in Zürich "pain tables," showing the number and duration of labour pains during each half-hour of labour, have been carefully kept since 1926. These "pain tables" show the number of pains necessary to complete the first, second, and third stages, the duration of the various stages, the amount of blood lost, and so forth, and a comparison is made with the results in 400 cases in which the membranes ruptured prematurely—that is, before the onset of pains. As to management, the author advocates hospital-care for all such cases and an expectant attitude with avoidance of vaginal examination. Hydrostatic bags find no favour and induction of labour by ecbolics or otherwise in the stage between rupture of the membranes and the onset of pains is deprecated. Judgment is reserved on manual dilatation when there are signs of foetal distress. Although reference is made to the unfavourable influence on the foetal mortality-rate it is disappointing to find no reference to the work of Warnekros and others on the frequency of placental infection when the membranes have ruptured prematurely, and to the consequent occurrence of maternal blood-stream infections, nor is there any note of British and American work on congenital infection of the foetal lungs.

Prof. W. H. Taliaferro's "Immunology of Parasitic Infections," reviewed in our last issue, is published in this country by Messrs. John Bale, Sons and Danielsson, Ltd., price 28s. post free.

THE LANCET.

LONDON: SATURDAY, APRIL 5, 1930.

THE PHARMACIST AND THE REPORT.

THE publication of the report of the Departmental Committee on the Poisons and Pharmacy Acts, of which a general survey was made in our issue of March 22nd (p. 633), had been awaited by pharmacists with impatience commingled with a certain amount of anxiety. This anxiety has, for the most part, been allayed by the presentation of the report, but there can be no doubt that pharmacists as a body would prefer the status quo to be preserved. In a few years from now the Pharmaceutical Society of Great Britain will be celebrating its centenary. It was in the early days of Queen VICTORIA's reign that a number of chemists and druggists met together at an hostelry in the Strand and resolved, on the motion of WILLIAM ALLEN, F.R.S., to form an Association for the purpose of protecting their permanent interests and—as it was quaintly put—of increasing their respectability. Less than two years from its foundation the Pharmaceutical Society was granted a charter of incorporation; quick work indeed, but it is to be recalled that the same WILLIAM ALLEN was instrumental in satisfying the Duke of KENT's creditors, and so contriving that the future sovereign should be born in the country over which she was destined to rule. Even so all was not plain sailing, and in our own columns appeared a warning of the supposed intention of the Society to sue for a charter and an advice to the Apothecaries Society to apply to the Privy Council before it was too late. The misunderstandings of ten decades back have long since been cleared away, and the Society has performed its duties honourably to the good of all concerned. What, then, is wrong with existing conditions, and why was the inquiry started? No charge of inefficiency had been laid against the Society, and there was no suggestion that the Pharmacy Acts were being administered improperly. Current stories of dope fiends and cocaine traffickers may have impressed the Government of the time, but there was nothing in the terms of reference to the Committee which had any bearing on the illicit traffic in narcotic substances, and there is certainly nothing in their report which would embarrass either the west-end charlatan who deals in "snow," or the Chinese keeper of an opium den. The cause of the inquiry remains obscure to the pharmacist. For 90 years the Pharmaceutical Society has been a voluntary body, and at the present time, to quote the figures in the report, there are 12,500 members, while 20,000 are eligible for membership. No pressure, except by way of gentle suasion, is brought to bear on registered chemists to join the Society, and the only means by which a chemist can show that he is a member is by displaying his certificate in his shop or by using the letters "M.P.S." after his name, if he so chooses. It is a remarkable testimony to the camaraderie of the pharmaceutical

profession and to the confidence it has in the Society that such a large proportion of those eligible for membership should pay a guinea and a half a year, when there is nothing stronger than a sense of loyalty to impel them to do it.

The Departmental Committee proposes to change all this; instead of volunteers we are to have conscripts and there is to be no loophole for the conscientious objector. From this principle there will be many dissentients, and they will be derived not only from the 7500 who at present benefit from the work of the Society without contributing to it, but also from the ranks of those who have supported the parent body because they considered it their duty to do so. In addition to compulsory membership of the Society, it is proposed to compel every person who owns a chemist's shop to pay a registration fee in respect of it. The maximum fee for membership is raised to £2, and the maximum fee for registration is £3. Thus, supposing the fees in each case were fixed at the highest figures, chemists owning single shops would be required to pay £5 a year, which, in the case of those chemists who do not now subscribe to the Society, would be a new charge; in the case of those who are members of the Society there would be a compulsory charge of £3 8s. 6d. in excess of the amount which they now pay voluntarily. A trifling calculation based on the figures given in the report shows that the Society's revenue from membership and registration fees would be £70,000, which, assuming that the present revenue from members' subscriptions is £21,000, would mean an addition of nearly £50,000 to its annual income. If such a proposal appears fantastic, there are two factors which must enter into the calculations. In the first place the amounts of the fees for membership and for registration are to be prescribed by by-laws of the Society; the maximum fees only are laid down in the recommendations of the Committee, and there is nothing to prevent the members of the Society, who elect the governing body, from so limiting the fees that the income from the two sources will not be greater than the present revenue from members' subscriptions. Thus it would be quite possible, though obviously not practicable, for the membership fee to be reduced to 15s. a year and the registration fee to be fixed at 7s. 6d., without loss of income; in such a case the present members would be in pocket to the extent of 9s. a year. In the event of the Bill which the Committee have drafted becoming law in its present form, the Society could be depended upon not to abuse the extraordinarily generous openings which the Committee propose to give them. The other factor is the increased cost entailed in the administration of the proposed new Act. While the onus of prosecuting offenders would be removed from the Society except as a "common informer," it would be charged with the duty of inspecting registered premises, and in proposing a registration fee the Committee had in mind the cost of this inspection. Further, it is clear that the addition of 7500 registered chemists to the membership list would entail a heavy cost, for clerical work and circularising alone would mean a substantial additional charge. The question of increased revenue is bound to be attacked when the Bill is debated in Parliament, for it will be argued by various trading bodies, which are jealous of the chemists' so-called privileges, that the revenue-raising powers with which it is proposed to endow the Society are too great. Were not the integrity of the Society itself a sufficient safeguard, it can hardly be seriously imagined that the members who, through

their elected representatives, make the by-laws, would consent to the imposition on themselves of heavy burdens, even though they feel, as they could feel, that the funds of the Society would be used for the advancement of pharmacy on a scale even more generous than in the past.

Turning to the administration of the law affecting the sale of poisons, the pharmacist will note that, whereas in the past the Society has been its own policeman, it is now proposed that the functions of prosecuting offenders should be handed over to the proper authority for dealing with infringements of the law. Such a proposal was inevitable as soon as an inquiry started, for although the Society has performed the functions of prosecution, judge, and jury for all these years with vigilance and justice, the system is out of tune with modern methods. Moreover, under existing conditions, the penalty for the offence in the majority of cases is an unalterable fine, and the offender is able to pay the penalty without incurring the more effective correction provided by publicity. The difference between the existing state and that proposed is the difference between a caning at home and sitting in the stocks, and while offenders would prefer to receive a demand by post for £5 rather than a summons from the hand of a policeman, it is frankly impossible to raise any logical objection to the proposed change. Some of the older members of the Pharmaceutical Society may regret the suggested intrusion of representatives of the Government into the domestic circle of the elected council. It is true that the Society's council and that august body, the Privy Council, have rubbed shoulders from the very beginning, but one may be friendly with a man without asking him home to dinner. The proposal, however, is in keeping with modern developments, and as it is impossible by any known method for a minority to outvote a majority, it is difficult to foresee that the presence of three nominees of the Privy Council will have any baneful influence on the 21 councillors elected by the members of the Pharmaceutical Society. In quite a different category

the contemplated constitution of the "Poisons Commission," which is something entirely new in pharmacy legislation. It is to consist of 14 or more members, of whom only five are to be appointed by the Society, and its duties will include the drafting of two lists of poisons; the sale of those in the first list will be restricted to registered chemists, but those in the second list may be sold not only by chemists, but by any person licensed for that purpose by a local authority. Chemists will claim a larger representation on this Board, notwithstanding that the nominees of the Pharmaceutical Society, together with those of medical bodies, will have a majority of two over the other members, unless the Home Secretary exercises the privilege of appointing four additional members. Hitherto the initiative in deciding what is a poison within the meaning of the Acts has been vested in the Society, and the change projected—namely, to give them only five-fourteenths of a voice, is so fundamental that it cannot go unchallenged. That, however, is an almost trivial matter compared with the encouragement which the recommendations, and Clause 16 of the Bill itself, holds out to potential vendors of poisonous preparations used for sanitary, industrial, horticultural, or agricultural purposes, or as sheep dips or vermin killers. As Mr. GAMBLE, whose association with a firm bearing the names of two of the founders of the Pharmaceutical Society is not without interest, says in his Minority Report: "any person will be able still more freely to purchase sufficient arsenical weed-killer to exterminate a

village" if Clause 16 is enacted. To us it appears inconceivable that it will become law in the form laid down in the Draft Bill. Already more than ample provision for the sale of industrial and agricultural poisons is available under an existing law, and it would be an act of folly to compel local authorities to grant licences for the sale of such poisons to all applicants, excepting imbeciles or criminals. The shops of trained and educated chemists are to be subject to a regular system of inspection, one of the objects of which is to ensure that poisons are properly "stored." Is it not far more important in the interests of public safety that purchasers of sufficient poison "to exterminate a village" should be required by law to store their purchases with extreme care, and to allow an inspection of the premises in which the poisons are stored, whether in an outhouse or in the larder?

MALARIA CONTROL IN INDIA.

THERE is a tendency to associate roving commissions with pleasant little excursions under the most comfortable conditions at the right time of year, punctuated at convenient intervals with complimentary dinners. But that this is not always a true picture is shown in an account of an Indian tour made by the Malaria Commission of the League of Nations last October, in the Singhbhum district of Bengal; the story is told by Lieut.-Colonel R. KNOWLES, the Editor of the *Indian Medical Gazette*, who accompanied the Commission, in the January issue of the journal. The Commission started work at the height of the malaria season, and their tour was evidently a very strenuous one. There were representatives from the United States of America, France, Spain, Holland, and Roumania. The members adopted a common-sense working kit; a photograph shows them all dressed in shorts, with open-necked shirts, no coats, and of course the universal solar topi for head covering. Starting from Calcutta they were taken, in a special train as headquarters, through some of the most malarious regions in India, varying between the rice fields which are so characteristic of Bengal, and picturesque hill and forest scenery. Close to Calcutta they were shown numbers of good-class Bengali houses lying deserted, the causes of abandonment, apart from the natural drift towards the city, being largely malaria and kala-azar. Graphic accounts are given of the wretched condition of the inhabitants of small villages in the worst-infected areas, and of the sufferings of the engineering staff at the time of the construction of the railway, due to malignant malaria and blackwater fever, but it is admitted that in most of these rural areas control on anything like a wholesale scale would be out of the question on the score of expense. One site fixed on for an important railway station had to be abandoned. Infection of running crews in the mining district of Noamundi is avoided by keeping the trains up at the mine heads in protected areas until they can get a clear run through by day.

Colonel KNOWLES's paper deals mainly with control measures at the Noamundi Mine, and, by contrast, at Dangoaposi railway station, through which passes an enormous amount of traffic connected with the mining area. The ground in the Noamundi region consists almost entirely of pure iron ore, which is worked from open quarries in the hillside. The chief source of malaria lay in innumerable seepages, and the bed of the river which they fed. This boulder-strewn stream

has been drained throughout the entire area, and every one of the seepages subsoiled—i.e., channels five feet deep and three feet wide are constructed, filled with boulders and covered with graded stones and earth. Neighbouring trees are dug out, and in that rocky ground it was necessary to use dynamite freely. Protective masonry walls were also built, when necessary, and everywhere seepage water has been led underground and delivered into the main stream through protected outlets. In short the entire hillside has been drained dry of water, thus constituting (with the addition of oiling where necessary, and the screening of all residential bungalows) the malarialogist's ideal of a malaria-free enclave within a malaria-ridden district. A diligent morning's search for mosquitoes by one of the Commission yielded only a single chironomid. It is stated that Noamundi Mine is now free both from larval and adult anophelines, and that the only cases which occur are relapses. These measures have, of course, been immensely expensive, and could only have been carried out where wealthy bodies such as the large steel and iron companies were concerned. The expense incurred must, however, have been repaid over and over again in the diminution of the sick-rate, which might otherwise well have rendered work impossible, as in the early stages of construction of the Panama Canal. Just outside the enclave is a village of aboriginals, where anophelines still breed freely, and there is an intense malaria incidence. The problems involved in mosquito prevention in the mine area are so largely of an engineering nature that the work has been put in charge of an engineering officer. He has unlimited labour at his command, and as much dynamite as he requires.

Malaria at Dangoaposi station is a different problem altogether. There, as Colonel KNOWLES says, it is man-made, as in so many other cases in India. The main trouble was a lengthy storm water channel, which was badly constructed, and an incessant source of mosquito breeding, and numerous borrow-pits by the side of the line. Malaria was so prevalent in 1925 that the incidence of attacks amongst the running employees in September was 287 per cent. for that month, which meant that each employee had approximately three attacks. Engines lay idle, and the mineral traffic was almost at a standstill. Control was commenced in November, 1925. Only two main measures were possible—the filling in of swamps and borrow-pits and the creation of proper storm water channels, with regular oiling. These procedures have been very successful, and Dangoaposi is now said to present a malaria control almost as perfect as Noamundi, at the comparatively slight cost of six rupees per head per annum of the population. Mention is made of a very remarkable phenomenon in this neighbourhood: a pool formed by an old manganese quarry, the water of which is absolutely inhibitory to the breeding of mosquito larvæ. Not only do mosquitoes not breed in the pool itself, but the water when turned into an adjoining stream apparently sterilises it of larvæ, while experiments carried out with the same water in shallow pools have shown that it retains its larvacidal properties for three weeks. The water has been analysed, and there is nothing unusual in its chemical composition. Colonel KNOWLES comments on the invaluable opportunities which tours of this description provide for workers in different countries to compare notes with each other, and remarks that this visit has afforded a most useful stimulus for the local observers. He considers the Noamundi scheme of control one of the most complete and perfect in the world.

REFLECTIONS ON CROTCH V. MILES.

ON mere academic grounds the case of Crotch v. Miles (fully reported in the last two issues of THE LANCET) may be deemed regrettably inconclusive. Two serious legal issues were raised but not decided. To begin with, was not the claim barred by the Statute of Limitations? The plaintiff began proceedings just eight years after the surgical operation of which she complained; the statute says proceedings must be begun within six years. Here there was an ingenious rejoinder. The surgeon, it was argued, committed an act of trespass by leaving the forceps in the plaintiff's body (if the jury should decide that he did); this trespass continued till the removal of the forceps in 1928, so that the six-year period did not begin to run until this recent date. The defence of a statutory time-limit (important in the Harnett litigation and crucial in cases where the Public Authorities' Protection Act is invoked) is not a mere technical plea. The Statute of Limitations was passed to check the abuse of raking up stale claims, it being unfair that a defendant should be attacked at a date when, by reason of lapse of time, his power of defence is prejudiced. Crotch v. Miles illustrated the unfairness; a witness on whose evidence the defendant would have strongly relied had died in the eight years interval. How can a surgeon, physician, or dentist be otherwise than at a grave disadvantage if suddenly called upon to meet an attack based on something which happened eight years ago?

The other important issue in the case—the question of the respective liability of surgeon and theatre sister for the counting of forceps and swabs—is also left in the air. A definite ruling, given by the Court of Appeal of South Africa in 1924, was cited to show that it is a reasonable and proper practice to leave the duty of checking swabs to the theatre sister. In the South African case the surgeon had made a careful search at the conclusion of the operation and had relied upon the sister to count and check in accordance with the usual hospital practice; the Court held that, though the operating surgeon was bound to exercise all reasonable and proper care, he was in these circumstances not guilty of negligence in respect of one swab which was overlooked. If that is the law in South Africa, is it also the law in England? We do not know. The second question which the jury was invited to answer in Crotch v. Miles raised the issue of the surgeon's responsibility for the task entrusted to the sister, but the answer to the first question made further answers unnecessary. Something like the same issue arose in a hot-water bottle case not long ago. Are the legal relations of surgeon and sister those of principal and agent or of master and servant, or neither? The legal theory, broadly, is that if A has only the right to direct what work B is to do, the relation is that of principal and agent; if A has the further right to direct how B shall do the work, the relation is that of master and servant. B may be the servant of A though C pays the wages and has the power to dismiss; and B may be simultaneously the servant of A and C for different purposes. The Lord Chief Justice seems to have advised the jury that the theatre sister is not a servant but "one of a team." The legal implications of this status remain obscure. The relationship is presumably a question of fact for the jury; if so, the decision may differ with the facts of each case.

The public will have noted Lord HEWART's remark that, if a forceps is left inside a patient, somebody must be liable. Intolerant of subtle divisions of

responsibility, the public may—if these unusual incidents recur—ask the profession to undertake some means of compensating the patient, though the evidence in *Crotch v. Miles* suggests that the scheme might have to be international in scope. Already the Law Society is considering some collective plan to reimburse those who lose by a solicitor's defalcations. And Parliament is busy with proposals for the universal insurance of motorists so that no injured person shall go uncompensated. The risk of loss, of course, is run by the surgeon as well as by his patients. He may incur huge expense in defending himself against claims for alleged negligence. Here, fortunately, a system of insurance exists; the surgeon can cover his risk by joining one of the professional defence societies. Mr. MILES's defence was undertaken by the Medical Defence Union through their solicitors, Messrs. HEMPSONS; his subscription to the Union has proved a sound investment.

Annotations.

"No quid nimis."

THE HICKMAN MEMORIAL.

It is impossible to estimate what mysterious moods will sway collective thought. We describe such a man as Galileo as born before his time, but it would be truer to say that his attempt to convince his fellows came during a refractory phase of the public temper. The times were not too early for his thought; they were simply "out of joint." It is a matter for speculation how many discoveries of value have been lost, swept away by a flood of untimely ridicule. Such was the fate of Henry Hill Hickman's work on anaesthesia at the beginning of the last century; and yet, less than 20 years later,

the rediscovery of his principle was to engage the interest and support of the whole scientific world. His work was remarkable for patient, careful experimentation; his belief that anaesthesia, or, in his phrase, suspended animation, could be used to spare patients the pangs of surgical operation led him to inquire into the action of carbon dioxide on mice and dogs. In his

HENRY HILL HICKMAN, M.R.C.S.
(From an oil painting in the Wellcome Historical Medical Museum.)

records experiments on a puppy a month old, which he placed on a piece of wood surrounded by water and enclosed in a glass cover; in ten minutes the puppy showed signs of uneasiness, and at the end of 17 minutes respiration ceased. Hickman was then able to remove one of the ears before returning respiration restored consciousness. Experiments made in a similar way, and others performed with carbonic acid gas, obtained from the action of sulphuric acid on lime, gave such good results that he

attempted to bring his discovery before the Royal Society, 1824, and in the same year he published his pamphlet on "Suspended Animation." No reference to his work has been found in the Royal Society's records, but apparently it was severely criticised in the reviews, and condemned as wild and impractical. In 1828 his faith in his principle led him to present a memorial of his work to Charles X. of France with an appeal to be allowed to develop his theories in the French medical schools. A commission was certainly formed to inquire into his discovery, but no report of their opinion has yet been found, and the interest excited was clearly not great. Hickman returned disappointed to England and died at the beginning of 1830.

His character, as indicated by his writings, was humane and kindly; in his pamphlet of 1824 he says: "if one grain of knowledge can be added to the general fund, to obtain a means for the relief of pain, the labours of the author will be amply rewarded"; and in writing of his experiments, he says they "were necessarily made upon living animals, but they were confined to animals previously condemned to death; and as their lives were preserved, and their suffering very slight . . . I venture to hope that they, in the aggregate, rather received benefit than injury." To his faith in his work he testifies in the last sentence of the pamphlet: "I feel so confident that animation in the human subject could be safely suspended by proper means, carefully employed, that (although I could not conscientiously recommend a patient to risk his life in the experiment) I certainly should not hesitate a moment to become the subject of it, if I were under the necessity of any long or severe operation." Yet in 1847 claims to the discovery of surgical anaesthesia were made by Morton, Wells, and Jackson in America, and in spite of the efforts of Dr. Thomas Dudley to direct attention to the earlier work of Hickman, the credit was apportioned unfairly. At the Wellcome Historical Medical Museum the documents relevant to Hickman's work are now exhibited. On the occasion of the centenary of his death on Wednesday Lord Dawson of Penn delivered an address at the Museum (see p. 770), when an admirably illustrated souvenir was offered to the guests. The Section of Anaesthetics of the Royal Society of Medicine are to place a memorial tablet on his tomb in Bromfield Churchyard to-day (Saturday) on the 100th anniversary of his burial. It is an easy matter to condemn our predecessors for lack of perception, but it engenders an uneasiness lest we are consigning our own prophets to the doubtful consolation of posthumous laurels.

PROF. W. H. WELCH AT EIGHTY.

THE eightieth birthday of William Henry Welch is to be celebrated on April 8th at several centres in Europe as well as in America. In London all who are interested are invited to attend at the London School of Hygiene and Tropical Medicine, at Keppel-street, W.C., at 4 p.m., when the Director, Sir Andrew Balfour, will give an address, with lantern illustrations, on Dr. Welch's life and work. The largest birthday gathering will be at Washington, when a meeting to be held in Continental Hall will be addressed by President Hoover, whose speech will be broadcast by radio across the continent, and relayed from the London Regional Station at 5 p.m. The chairman of the committee in charge of the arrangements is Dr. Simon Flexner, and the opening address is to be given by Dr. Livingston Farrand, president of Cornell University. A special feature of the occasion will be the presentation to Dr. Welch of the first print from a dry-point etching portrait of him made by Alfred Hutty.

William Henry Welch was born in Norfolk, Connecticut. His father was a practising doctor, as were also four uncles, a grandfather, and a great-grandfather. He entered Yale University at the age of 16, and four years later graduated B.A. After a

year spent in teaching Greek and Latin he matriculated in the College of Physicians and Surgeons of New York, but quickly realised the need for a better scientific foundation, and went back to Yale to study chemistry. Returning to New York in 1872 he won the award of a microscope, then a comparatively rare instrument, and with it began his notable career in the new science of pathology. In the early summer of 1876 he reached Strasbourg and studied histology and physiological chemistry under Waldeyer, Hoppe-Seyler, Baumann, and von Recklinghausen. Later he went to Leipzig, where he worked under Wagner and Ludwig. The next year found him at Breslau working under Cohnheim, who was then engaged on his text-book of general pathology, and already Welch's own contributions to bacteriology were considered worthy of being incorporated in the book. On his return to America he spent six years in the laboratories at Bellevue College, and in 1884 accepted the post of pathologist at Johns Hopkins Hospital. Before beginning his work at Baltimore in the autumn of 1885 he returned to Europe for further post-graduate study under Pettenkofer, Flüge, and Koch. He became the principal adviser in the early development of the Johns Hopkins Hospital, and in the selection of the other three original members of the staff, Osler, Halsted, and Kelly. When the medical school was opened in 1893 Welch was its first dean. His career from that time on in medicine and public health is well known. His resignation of his post as director of the school of hygiene four years ago was merely the opportunity for new efforts and the founding of a new institution. As professor of the history of medicine he set to work with characteristic energy to make a marked success of the new medical library at Johns Hopkins which was dedicated six months ago and named after him. He is still one of the most active figures in American medicine, and we trust he will long continue his public work.

A NEW ANTISEPTIC FOR INTERNAL USE.

THE announcement of the discovery of a new antiseptic for internal use always arouses considerable interest. The essential properties of low toxicity combined with high germicidal powers are so difficult to find in any one substance that the use of internal antiseptics is now on the decline. At the present time they probably find their greatest application in the treatment of infections of the urinary tract; but here again it is difficult to find any substance sufficiently non-toxic and non-irritating to the gastrointestinal tract to ensure excretion in the urine in sufficient strength to destroy the invading organism. Of recent years attention has been directed towards the members of the homologous phenols. The first substance to find extensive employment was hexylresorcinol, an antiseptic introduced into medicine through the work of Johnson and Lane in 1921,¹ and Dohme, Cox, and Miller in 1926.² By studying the influence of alkyl substituents upon the germicidal value of resorcinol, they showed that it rose to a maximum at 4-*n*-hexylresorcinol, and also that the antiseptic powers of the *n*-alkylresorcinols were greater than those of branched-chain alkylresorcinols having the same number of carbon atoms. Coulthard, Marshall, and Pyman³ thought that an investigation into the effect of alkyl substituents upon the antiseptic value of phenol and its homologues might yield valuable results, as information upon this subject was very scanty. They used the Rideal-Walker technique for the determination of the phenol coefficients, but solutions in dilute aqueous sodium hydroxide were employed, care being taken to keep the concentration of sodium hydroxide below lethal strength. All the alkyl derivatives were prepared by reduction of the corresponding ketones by

Clemmensen's method. It was found that the phenol coefficients of the *n*-alkylresorcinols were generally higher than those of the corresponding *p*-*n*-alkylphenols, and very considerably higher than those of the *n*-alkylguaiacols, and, further, that the antiseptic powers of the compounds generally increased with the number of carbon atoms in the side chain up to the *n*-amyl derivative and then diminished. 4-*n*-amyl-*m*-cresol was studied in some detail, and proved to have phenol coefficients of from 200-300 not only when tested against *B. typhosus* but also against streptococci and staphylococci. Moreover, as compared with other substances, it has a low toxicity, and so would appear to be an important discovery from the point of view of medicine. Dr. Pyman, in an article in the current number of the *Journal of the Society of Chemical Industry*, points out also that it possesses a pleasant taste, which would make it very suitable for use in mouth-washes and similar preparations. In order to test its bactericidal action, varying solutions were added to 5 c.cm. of a mouth-washing, shaken up, and the number of colonies at the end of 5 and 15 minutes counted. A striking reduction was observed with solutions of 1:10,000 and 1:20,000. It will be interesting to observe experiments on its value as a urinary antiseptic.

HEALTH OF THE NAVY.

THE Statistical Report of the Health of the Navy for 1928¹ having now appeared (speeded up some three months on its predecessor) it is possible to compare the sickness and mortality-rates in the three Services for the year 1928.

Rates per thousand.	Cases.	Deaths—	
		Total.	From disease.
Navy	446	2.22	1.34
Army	426	2.3	1.63
Air Force	430	4.49	1.31

Both case rates and invaliding rates are diminishing in the Navy, and the death-rate from disease is the lowest yet recorded. The death-rate from violence is apparently only a quarter of that among British seamen in the mercantile marine during the same year. The number of men in the Navy in 1928, was 90,820, a decrease of about 2400. The chief causes of invaliding were as follows: 214 for diseases of eye; 119 for pulmonary tubercle (22 for non-pulmonary); 111 for diseases of the ear; 74 for wounds and injuries. Deaths were due in 50 cases to injury, in 17 to pulmonary tubercle (3 non-pulmonary), in 15 to pneumonia, in 15 to disease of intestines; 14 deaths were suicidal, 11 men were drowned. Vaccination against small-pox is now repeated every five years, with a single insertion which will involve less loss of service. Though vaccinations and revaccinations increased from 12,000 in 1927 to 19,000 in 1928, the resulting loss of service was reduced by a half. Three cases of small-pox were seen in China, of which one died. Diphtheria has, it is hoped, been banished from Greenwich Hospital School by Schick testing and immunisation; toxin-antitoxin floccules is regarded as the production of stimulating antitoxic immunity better than toxoid, and without causing reactions. A case of cutaneous diphtherial ulcer was recognised in hospital and cured with antitoxin, but no carriers were found in the ward. Of typhoid fever there were three cases with one death, of paratyphoid four cases. The cases of influenza numbered one-fifth only of those in 1927; they occurred chiefly at home. Malaria increased slightly, most of the cases coming from West Africa; in spite of prophylactic quinine, supervised mosquito nets, and other precautions, there were 41 cases on a sloop. A stoker who died of heat stroke in the East Indies showed post-mortem

¹ Johnson and Lane: Jour. Amer. Chem. Soc., 1921, xliii., 348.

² Dohme, Cox, and Miller: Ibid., 1926, xlviii., 1688.

³ Coulthard, Marshall, and Pyman: Jour. Chem. Soc., February, 1930, p. 280.

subtertian parasites in the spleen. Cases of pneumonia were fewer, total 1.94 per 1000; at home, 2.63; abroad, 1.5. Rheumatic fever, with a case rate of 1.14, occurred about equally abroad and at home. Pulmonary tuberculosis shows much the same figure as last year, but invaliding is less. The chief incidence was on seamen, with 77 cases (2.05), the most dangerous age being between 20 and 25, but with increasing liability after five years' service. All three Services have reported specially on tubercle this year, and all find pleurisy to be a frequent precursor; seven years ago, in 1921, there was no special report on tubercle from any one of them,² and in all the prevalence of tubercle has since been much reduced—in the Army from 2.0 to 1.1; in the Navy from 2.38 to 1.99; in the Air Force from 1.7 to 1.1. Two of 20 cases in the Air Force at home, and 11 of 153 cases in the Navy, had a family history of tubercle. For venereal disease the figures are much the same as last year; all varieties are more frequent abroad than at home—chancroid three times, gonorrhoea twice, and syphilis slightly. The lowest case ratio is claimed for the Atlantic fleet (41.22), but that for marines at head quarters is lower (25.12). Invaliding for syphilis is stated at nine, but eight further cases of locomotor ataxia are mentioned among the nervous diseases. Of encephalitis lethargica, 16 cases are mentioned, 11 were invalided, and one died. Two cases of plague in natives ended fatally at Bombay, infected in a rat-infested boarding-house. Of disseminated sclerosis seven cases occurred. Teeth conserved were 61,664, or 676 per 1000 men; in a group of about a thousand mouths examined specially, 36.23 were dentally fit, 59.08 required treatment (3.44 urgently), 4.65 required dental work. Scabies cases average six days under treatment. Poisoning and suicide have increased from 62 and 7 to 101 and 14 cases. Injuries and heat stroke are much reduced. The leeway of war time is being overtaken, this report (as already noted) following its predecessor in three months less than a year; but there is still no sanitary report on the cadets at Dartmouth.

THE COMPLEMENT-FIXATION TEST IN GONORRHOEA.

SEROLOGICAL reactions for the diagnosis of gonococcal infections have received rather scant attention in this country. In the October number of the *British Journal of Venereal Diseases* Dr. T. E. Osmond and Dr. J. O. Oliver have reviewed the results of testing over 5000 sera from unselected patients, some of whom suffered from gonorrhoea or syphilis or both diseases, others giving no history or evidence of venereal disease. A full description of the technique adopted is given, and the importance of the antigen used in this test is stressed. The method of preparation used is that of D. Thomson, in which suspensions of the organisms are dissolved in alkali and afterwards neutralised to an exact pH of 7.0. Many separate antigens are prepared and each is tested; those giving satisfactory results with the preliminary testing are pooled. The importance of using multiple strain antigens is very great, and, as a rule, not less than 12 selected ones should be taken for the preparation of the mixed product. This pooled antigen must be examined in parallel with a mixed antigen of known value in a considerable number of cases, or tried out against many sera from cases studied clinically when no previous antigen is available as a standard. From a classification of results into groups the remarkable specificity of the test becomes apparent, since the percentage of falsely positive results obtained is as low as 0.6 per cent. In all cases beyond the earliest stage a high proportion of positive results was obtained ranging from 50 to 95 per cent. in cases of definite gonococcal infection with complications. Up to the tenth day of the disease a positive result is not to be expected unless complications have already occurred; the incidence

of positive results during this period is higher in males (13.9 per cent.) than in females (4.3 per cent.). An early positive reaction almost invariably indicates extension of the disease to the posterior urethra in the male or to the cervix uteri in the female. From the tenth to the twenty-first day of the disease is the commonest time for the appearance of the positive reaction, males giving 50.1 per cent. and females 54.3 per cent. These figures rise to 70.5 per cent. for males and 56.4 per cent. for females, when infection has lasted up to a year. Owing to the specificity of the test a positive result in any stage of the disease is practically diagnostic, whilst a negative reaction resembles a negative Wassermann reaction in that it may occur at any stage. Its diagnostic value is limited except in the differential diagnosis of complications such as arthritis or epididymitis, for in these a positive result is found in 95 per cent. of cases. Considerable difficulty exists with regard to the disappearance of a positive reaction with cure. Dr. Osmond and Dr. Oliver differ from certain other observers in that they do not regard the persistence of a positive reaction as proof of failure of cure. They regard the gradual falling off in the positive reaction as a normal event in many cases which subsequent history suggests were in reality cured. Cases are quoted which show that the disappearance of a positive reaction may be a slow process. Stock vaccines are thought to influence the reaction much less than autogenous ones. A negative reaction in a patient who has once shown a positive one is of great value as a criterion of cure.

NARCOTICS IN ASIA.

THE Society of Friends has for many years taken a deep interest in what is known as "the opium problem," and several of its members took an active part in the movement which led up to the abandonment of the Indo-Chinese opium trade. Among these was the late Mr. J. G. Alexander, the father of the author of a brochure recently published.¹ With the assistance of a travelling scholarship awarded to him by the Selly Oak Colleges, Mr. H. G. Alexander visited India, Rangoon, Malaya, and Java during 1927-28 with a view to making independent investigations of the present position of the opium question in those countries. As a result of this tour he is less severely critical of the opium policy of the Indian Government than are some of the more zealous writers on the subject. While rejecting the plea of the Royal Commission of 1895 that opium is a prophylactic against malaria, he considers the pernicious effects of opium-smoking and opium-eating as less disastrous, socially and morally, than the wholesale abuse of morphine, cocaine, and heroin, with which western countries have flooded Egypt, India, China, and the Far East. Mr. Alexander, nevertheless, condemns what he regards as the contradictory policy of the Indian Government in urging decreased consumption on the one hand, while "its agents are trying to push sales in order to increase revenue" on the other. In some parts of India, notably the United Provinces, Mr. Alexander was informed that cocaine addiction was "spreading like wild-fire"; huge figures indicating the extent of the illicit traffic and police seizures have been published, and according to the United Provinces Excise Report most of this contraband cocaine comes from Germany, Italy, and Japan. The allegation that India is being swamped with opium smuggled from China is here disputed; careful inquiries were made by Mr. Alexander and the conclusion was reached that illicit traffic proceeds from Persia and Rajputana. The cessation of the Indo-Chinese trade in 1907 left large stocks of opium in the hands of the merchants in the Malwa States which are outside Government control.

¹ *Narcotics in India and South Asia*. By H. G. Alexander, M.A. London: Williams and Norgate, Ltd. 1930. Pp. 64. 2s. 6d.

² *Tuberculosis in the Services*. See THE LANCET 1924, II., 664.

It is contended that from this source opium is being smuggled to many parts of the world, including South Africa, Australia, and other distant countries, as well as to British India. The author states that while in nearly all great cities of India opium addiction is common, in some it is serious, and that in the upper part of the Assam valley opium consumption is heavier than in any other part of British India. Parts of Orissa, of Berar, and of the Punjab are also black spots in this respect. The remedy suggested is registration and rationing, and in the cities the transfer of sale of opium to druggists, who should sell it only under medical prescription. In conclusion Mr. Alexander, while not minimising the evils of opium-eating and opium-smoking, insists that the "main guilt" lies with Western nations, who are making large profits by the excessive manufacture of morphine, heroin, and cocaine, and exporting these alkaloids by the ton, and by clandestine methods to the detriment of the native populations of Asia. His views are conceived in a more dispassionate spirit than are many of the disquisitions of lay writers on the opium problem and deserve attention. The message of this book confirms the conclusion which the Advisory Committee on opium at Geneva appears at last to be formulating, that, as The Hague Convention of 1912 implied, control of narcotic drugs at the source is the only way to restrict their use to legitimate medical purposes.

THE SLUM CLEARANCE BILL.

THE text of the Government's new Housing Bill was issued on Tuesday last, and Mr. Greenwood, the Minister of Health, will move the second reading next week. The measure, in addition to dealing with slum clearance and improvement, also contains provisions in regard to rural housing and small houses for aged persons. There are 56 clauses and five schedules, and the Bill is accompanied by a financial memorandum. The Bill is drafted with a view to enabling local authorities to direct their attention first of all to areas where conditions are so bad that the only remedy is clearance; secondly, to improvement areas, semi-slum areas which are degenerating into slums, partly because of overcrowding, and partly because of unsatisfactory buildings; and thirdly, to individual houses which are in need of repair, or are so bad that they must be demolished.

The first part of the measure deals with clearance areas and improvement areas, and the second part with individual insanitary houses. The definition of a clearance area is substantially the same as that of an unhealthy area under the existing law. The area can be cleared either by requiring the owners to demolish the buildings, or by the local authority purchasing the area and arranging for the demolition. The first method is new and is intended to enable local authorities to remove bad slums without being obliged to incur the heavy capital expense of purchase and clearance. The local authority will make a clearance order which must be confirmed by the Minister of Health—after a local public inquiry if objections are raised. When an order has been made it will be the owners' duty to demolish the buildings. If they fail to do so the local authority will be empowered to demolish and to recover the cost. The cleared site will remain with the owners who may, subject to local by-laws, dispose of it or redevelop it at their discretion. The second method of dealing with a clearance area will be by purchase by the local authority which would itself undertake the removal of buildings on the site. The procedure is intended to be more simple and expeditious than that at present in operation, and does away with the necessity for a formal scheme. The local authority having bought the land by agreement or by compulsion must proceed to demolish the buildings, and either appropriate the land for some purpose for which they have statutory powers, or otherwise

dispose of it. In some cases they may have to rehouse on the site, or they may maintain it as an open space. Clauses 5 and 6 deal with improvement areas—those districts where the general conditions are not so bad as to justify wholesale clearance, and where a great improvement can be secured if the worst houses are removed, necessary repairs are executed, surplus population removed from the area, and steps taken to ensure that once the area has been improved it is not allowed to relapse. An essential part of any action taken by local authorities in regard to either clearance or improvement areas must be the provision of new houses, and the Bill requires that before taking any steps involving the displacement of population the local authority must undertake to provide new dwellings to the satisfaction of the Minister. Clause 5 enables local authorities to define improvement areas, and Clause 6 sets out the action which must be taken, when an area has been defined, to compel the demolition of houses which are beyond repair, and to put other houses into a satisfactory condition. It is not proposed to make any change in the present law of compensation for property in a clearance area. Property compulsorily acquired in such an area will be purchased site value with a reduction where the proposals involve the use of the cleared area for rehousing purposes or for an open space. Local authorities will, however, be enabled to make reasonable allowances to displaced persons for removal expenses and to compensate any loss which, in the opinion of the local authority, may be sustained by such persons owing to disturbance to their trade or business.

The second part of the measure proposes to alter the present law with regard to the repair and demolition of individual insanitary houses. The object will be to simplify the procedure, and it is provided that the appeal tribunal shall be the county court instead of the Minister. Houses which are considered unfit for human habitation may be divided into those which can be made fit at a reasonable expense and those which cannot. In the case of houses in the first class local authorities may require the owner to carry out the necessary work or, if the owners fail to do so, the authority may do it themselves and recover the cost. In suitable cases money may be lent to owners undertaking repairs. If the house cannot be made fit at a reasonable cost, the local authority may enforce an order for its demolition. The third part of the measure provides that the council of every borough and urban district (and in London the City Corporation and County Council) with a population of more than 20,000 shall submit a programme of housing work to the Minister in 1930 and every fifth year thereafter.

A new principle underlies the financial provisions of the Bill by which the present 50 per cent. grant is to be abolished and replaced by an annual grant on a unit basis, which the associations representing the local authorities are willing to accept. The new grant is to help towards the expenses incurred by local authorities in rehousing persons displaced from clearance areas; improvement areas and also individual insanitary houses outside those areas which are demolished by order of the local authority. The grant will be based on the number of persons required to be displaced for whom accommodation in new houses provided by the local authority is made available, and will be payable annually for 40 years. The normal grant will be 45s. a year per person required to be displaced, and this will be increased to 50s. in the case of persons displaced from houses in agricultural parishes. Where it is necessary to rehouse on expensive sites in tenement buildings of more than three storeys, or where the approved cost of the site exceeds £4000 an acre, the grant will be increased to 70s. per person. The object of this is to meet the special cases where people must be rehoused as near as possible to their work. Certain special conditions must be observed in regard to houses made available for displaced persons. Rents must be fixed by the local authority after taking into

account a charge on the rates of not less than the equivalent of £3 15s. a year for 40 years, the normal charge borne by the rates for houses provided under the Wheatley Housing Act. The Government believe that the increased assistance proposed will enable the authorities to provide a proportion of houses at "Wheatley" rents, and others at a definitely lower rental. Assistance is to be granted through local authorities to societies and companies engaged in housing who limit the amount of their dividends or who do not trade for profit, and who are willing to help in the work of rehousing persons displaced from slum areas. In Clause 39 there is a proposal to build houses for aged persons of a smaller size than the minimum in respect of which Exchequer assistance can now be given. The present Exchequer contribution is £7 10s. a year for 40 years. In respect of the new smaller houses it will be £5 a year for 40 years, equivalent to a capital value of £86.

A further attempt is to be made to deal with rural housing, and it is proposed to place a new responsibility on county councils by giving them power to undertake building on behalf of a rural district; by enabling them to contribute to the expenses of ordinary rural housing, and by putting an obligation on them to contribute to houses provided by rural councils for agricultural workers, or persons of similar economic status. It is proposed that the unit grant shall be reviewed every three years and at the same time the period at which the Wheatley grants are reviewed will be increased from two to three years. The Bill does not apply to Scotland, which is to be dealt with in a separate measure.

IN THE INTEREST OF MIDWIVES.

IMPROVEMENT of the midwifery service of the country requires united action on the part of all those interested in order that urgent problems may be dealt with promptly as they arise. This aim has led to the formation, at the instance of the Council of the Midwives Institute, of a joint committee representing the following bodies: Association of Inspectors of Midwives; Association for Promoting the Training and Supply of Midwives; the College of Nursing; the Incorporated Midwives Institute and the Queen's Institute of District Nursing. The objects of this joint committee, on which six additional members have been co-opted, are: (1) To support all schemes which in the opinion of this committee will genuinely promote the welfare of mothers and midwives; (2) to oppose any legislation involving transference of the control of the profession of midwifery from an independent body to a Government department; (3) to formulate proposals for the reorganisation of the special body which should have control over midwives and their training; and (4) to endeavour to arouse public opinion in support of the above objects. The committee has already received wide support for its policy on object (2). The committee is in entire agreement with the report of the departmental committee in so far as it relates to a comprehensive and national maternity scheme, provided that the legislation introduced is in accordance with the proposals outlined which are briefly as follows:—

- (a) Medical examinations during antenatal period.
- (b) The mother to retain a cash maternity benefit and in addition to be given the full services of a certified midwife or, alternatively, a doctor and a midwife acting as a maternity nurse.
- (c) The services of a doctor when required.
- (d) The services of a specialist on the doctor's request.
- (e) Institutional provision for the confinement of abnormal cases, patients with unsuitable home conditions, and also for those who desire such arrangements.
- (f) Further medical examination six weeks after the confinement.
- (g) The midwife to be responsible for antenatal and postnatal care and nursing to cover a period of 14 days with increased number of visits.

On the other hand, the committee is not in favour

of the proposed limitation of the midwife's cases to about 100 in the year, preferring the general acceptance that no midwife should undertake a larger number of cases than she can adequately deal with, in view of the additional work to be put upon her. The committee would make obligatory the following permissive provisions under the Maternity and Child Welfare Act—namely, subsidies to midwives in rural areas, the provision of sterilised maternity outfits to mothers free or at cost price, the payment of part or the whole of the fee to the midwife when the patient is necessitous, and the provision of post-certificate training for midwives. Local authorities should be empowered to give compensation for the midwife if a case for which she was engaged is sent to an institution, to provide for her in old age and sickness, and to assist in transport and telephone service in rural areas. The committee is of opinion that the Central Midwives Board or any new special body having control over midwives should retain the whole duties connected with the training, penal work, and the examinations and government of the profession. Such a body should, it is felt, consist as in the past of representatives from the Government, the midwives, the medical profession, and local authorities. Finally, the committee expresses the hope that the inspection of new training centres which apply for permission to train pupil midwives will be extended to all training schools, teachers, and systems of teaching.

Lady Houston has given £100,000 to St. Thomas's Hospital, London. The gift has been made without conditions, and will be paid into the general fund of the hospital.

WE regret to learn the death, which occurred on Sunday last in a nursing home, of Dr. John Yule Mackay, the well-known anatomist and Principal of University College, Dundee. For many years Prof. Mackay's share in the deliberations of the General Medical Council was recognised as authoritative on all educational questions.

THE first international Congress of Microbiology will be held in Paris from July 20th to 25th. Arrangements for attendance are being made by the British Committee of the International Society for Microbiology, and any who desire to take part in the Congress should apply to Messrs. Thos. Cook and Son, Berkeley-street, London, W.1, or to any of their branches.

THE first Congress of the International Society of Orthopaedic Surgery, under the presidency of Sir Robert Jones, will be held in Paris from Oct. 2nd to 4th next. The vice-presidents of this Society are Prof. V. Putti, of Bologna, and Dr. Gocht, of Berlin, the secretary-general is Dr. Delchef, and the treasurer Prof. Maffei, both of Brussels. Subjects chosen for discussion at this congress are: (1) Treatment of congenital dislocation of the hip after the age of 15 years. On this subject America, Germany, Great Britain, and Italy have been asked to supply speakers. (2) Treatment of injuries in the region of the wrist-joint, which will be discussed by representatives of France, Holland, and Sweden. The Secretary of the Congress is Dr. Albert Mouchet, rue de Courcelles 124, Paris.

ROYAL FREE HOSPITAL.—The annual Court of Governors was attended last week by the American Ambassador and Mrs. Dawes, who visited the Eastman Dental Clinic, the gift of Mr. George Eastman, of Rochester, New York. The new obstetric department has been begun, and it was reported that the 365 beds are always full. The 1928 deficit of £16,595 has been reduced to £7538.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lts. to be Surg. Lt.-Comdrs.: J. G. Holmes, R. G. Anthony, and E. R. Sorley.

The following appointments are notified: Surg. Lts. C. J. Farr to *Verdena*; N. A. Dickinson to *Pembroke*, for R.M. Infirmary, Chatham; and R. B. McVicker to *Veronica*.

ROYAL ARMY MEDICAL CORPS.

Maj. W. J. E. Bell, from the seed. list, is restd. to the establt.

Maj. A. F. I. Patterson retires, receiving a gratuity, and is re-empld. under Art. 607 (b), Royal Warrant for Pay and Promotion.

Lt. W. H. Scriven is seed. for serv. with the Sudan Def. Force.

TERRITORIAL ARMY.

Capt. P. Lloyd-Williams, W. R. Watt, and J. T. Kyle to be Maj. s.

Capt. R. W. Gemmell (late R.A.M.C.) to be Capt.

Lt. R. E. Holme to be Capt.

Lt. R. V. Facey (late R.A.F.) to be Lt.

W. W. Crawford to be Lt.

Superannuary for Service with O.T.C.: J. P. Raban (late Offr. Cadet, Lond. Univ. Contgt., Sen. Div., O.T.C.) and H. H. Kenshole (late Offr. Cadet, Univ. of Lond. Contgt., Sen. Div., O.T.C.) to be Lts., supern. for serv. with Med. Unit, Univ. of Lond. Contgt., Sen. Div., O.T.C.

ROYAL AIR FORCE.

Flight Lt. E. J. T. McWeeney is transferred to the Reserve, Class D.

INDIAN MEDICAL SERVICE.

Capt. A. K. Sahibzada to be Maj.

The probationary appts. of the undermentioned officers are confirmed. The order of seniority is as now notified:—To be Capt. s.: F. R. W. K. Allen. To be Lts.: A. V. O'Brien, S. T. Davies, E. S. S. Lucas, H. W. Farrell, J. S. McMillan, V. E. M. Lee, M. R. Sinclair, G. B. W. Fisher, R. A. Paton, G. F. Condon, H. S. Smithwick, and D. Tennant.

DEATHS IN THE SERVICES.

Fleet-Surg. Alfred Thomas Corrie, R.N. (ret'd.), who died at Plymouth on March 29th, entered the Navy as surgeon in 1872. He served in the corvette *Pearl*, and was present at Santa Cruz, South Pacific, when an attack was made on shore by natives. This resulted in the death of the Commanders and two men, and Corrie was placed in medical charge of the boats sent to punish the outrage. For some time he was surgeon at the Plymouth Naval Hospital, to the Royal Marine Artillery Infirmary at Eastney, and to the R.N. Hospital, Ascension. He was promoted to staff surgeon in 1884, fleet-surgeon in 1892, and retired in 1902.

ROYAL MEDICAL BENEVOLENT FUND.—During the first quarter of this year £2562 has been voted in grants to 121 applicants. At the last meeting of the committee 42 grants were voted, amounting to £866. The following were some of the cases helped:—

M.R.C.S., aged 76. Married, wife aged 66. Applicant suffers from advanced chronic glaucoma. He has lost the sight of his right eye. Although maintaining some sight in his left eye he is becoming more helpless and dependent on others. Applicant and his wife have no private income; he is in receipt of Old Age Pension £26 a year. Four married children contribute £96 towards the maintenance of their parents. Fund voted £40.

M.R.C.S., aged 59. Applicant is bedridden and is suffering from progressive paralysis in the legs. He was compelled to give up his practice in 1925. His savings had been invested in house property. The fall in values and the annual outlay in repairs has reduced the income derived therefrom to £130. Being bedridden he has to pay for nursing and attendance in addition to board and lodging. Fund voted £20.

Widow, aged 38, of M.R.C.S. The husband had been ill for several years with Bright's disease. On his death the widow was left with £250 a year and eight children to educate. One has obtained a Scholarship. Freemasons are paying part school fees for another. Friends and relations are helping towards other school fees. Fund voted £25 and have asked the Royal Medical Benevolent Fund Guild to co-operate in this case.

Daughter, aged 61, of M.D. Has been a companion house-keeper from the date of her father's death till December, 1929, when her employment terminated. She has no private income, now staying with friends. Fund voted £26.

Subscriptions and donations are very urgently needed as the number of applications received during the first three months of this year is even larger than that of last year.

Cheques should be forwarded to the honorary treasurer, Royal Medical Benevolent Fund, 11, Chandos-street, Cavendish-square, London, W. 1.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCCL.—THE TREATMENT OF SYPHILIS.*

IN a short article it is possible to deal with only a small section of such a vast subject as the treatment of syphilis. I am here concerned mainly with generalisations and principles. I will speak first of the principles of treatment of early syphilis—i.e., of the so-called primary and secondary stages.

TREATMENT OF EARLY CASES.

Lessons from Experimental Syphilis.

Certain investigations in experimental syphilis seem to have a bearing on the problem in the human subject. The observations of W. H. Brown and L. Pearce on the course of syphilis in rabbits after experimental inoculation showed that it resembles the course of another spirochaetal disease—relapsing fever—in its succession of phases of active disease alternating with phases of latency. In the rabbit the disease seems to become active in tissues according to a more or less regular order of sequence. Thus, in cases where manifestations become generalised, after the primary lesion, bones, followed by skin and then eyes, appear to become affected.

A further point of some importance is that the successive phases of activity are influenced in their locality and degree by the degree of severity of their predecessors. Thus Brown and Pearce found that if a rabbit has two primary sores it is much less likely to develop generalised lesions than if it has only one. Further, if the development of the primary lesion or lesions is interfered with, by excision of the area of inoculation or by administering antisyphilitic remedies in subcurative doses, the rabbit is much more likely to develop generalised lesions. Brown and Pearce found, in fact, that they could more or less determine the locality of metastatic lesions by interfering with the primary sore at given stages of its development. Thus by fairly early interference they would find the bones unprotected, and metastatic lesions would occur there. If subcurative treatment was withheld until a little later, the metastases would skip bones and occur in the next tissue in the natural order of sequence for lesions in the rabbit—viz., skin—or the skin might be skipped and the eyes become affected. Brown and Pearce's investigations showed, in fact, what has been demonstrated by numerous workers, that the syphilitic animal develops a resistance to the spirochete of syphilis which is proportional to the degree and duration of the interaction between spirochaetes and tissues. As another example of the same effect is the fact that a syphilitic rabbit can be super- or reinfectd at an early stage of the infection, but if one waits for about three months before eradicating the disease it has now become immune to reinfection with, at any rate, the same strain of virus.

I suggest that this has a bearing on the treatment of human syphilis in this way. We know that the virus spreads through the body very rapidly. For example, changes in the cerebro-spinal fluid have been demonstrated even as early as the primary stage before the serum reactions have become negative, and we must suppose that at the time we commence the treatment of our early case there are nests of spirochaetes in practically every tissue of the body. We have also good reason for believing that some foci are less accessible to our remedies than others and that amongst the less accessible are those in the central nervous system. If we were to allow the disease to take its natural course, we should expect in most

* The substance of this article formed the opening address in a discussion at the Medical Society of London on Feb. 24th.

cases a widespread eruption on the skin and mucous membranes. I suggest that the effect of this eruption would be to confer a strong degree of resistance on the tissues generally, including those of the central nervous system, and this idea is certainly favoured by the fact that in cases of late neurosyphilis such as tabes and general paresis one rarely finds a history of secondary symptoms.

So far the argument has favoured the idea that, if we interfere with the development of the disease in the skin and mucous membranes, we interfere with the development of a resistance to the activity of the parasite in other parts of the body which would tend to save him from severe late effects of the disease in such vital structures as central nervous system and cardiovascular system, and there are some who even say that if they had syphilis they would not commence treatment until the secondary stage was well over. I wonder if they would if it came to it. There are many reasons against such a procedure, the most important being the danger to other persons, the greater opportunity given to the spirochæte to become protected in foci of fibrosed tissue, and therefore inaccessible to later attack, and also the possibility that, after all, the skin reaction might not take place. When we weigh up the question of early interference by treatment versus allowing the disease to develop I do not think we can avoid deciding in favour of early interference. But we must keep in mind the risk we run of leaving the less accessible foci untouched by our remedies and unhampered in their development by the antibodies which would probably have formed if we had let the disease have full play with the skin. The moral seems to be that, if we interfere early, we must do so thoroughly and with the proper remedies.

Remedies Employed in the Treatment of Syphilis.

In considering the remedies and their place in the therapy of early syphilis, I would divide them into two main classes, antispriochætal and tissue stimulant. In the antispriochætal are mainly the preparations of arsenic, mercury, and bismuth, as well as a certain number of other metals such as vanadium, tellurium, and gold which have not come into general use. Amongst the tissue stimulant is pre-eminently iodine, and we should also include all preparations designed to raise the general resistance.

I would divide the antispriochætal preparations into two main classes, the arsenobenzols and the others. The arsenobenzols are distinguished from the others by the rapidity of their effect, but mainly also for its transience. The spirochæticidal effect of an arsenobenzol injection is dramatic so far as we can judge from examinations of the secretion from surface lesions, but it is over in at most 48 hours. If the dose is large enough it brings to an abrupt end the interaction between the spirochætes and the surface tissues. But does it kill off so easily those spirochætes which are buried in the central nervous system, and the cardiovascular system, and perhaps the viscera? The literature on early syphilitic neuro-recurrences shows that in the overwhelming majority of cases they have occurred in cases treated only with arsenobenzol preparations. The patient has fallen between two stools, the development of a protective immunity has been stopped, and its substitute has been insufficient to destroy foci in the meninges. These nests of spirochætes have quickly recovered and have been unrestrained by any immune body. We have here, in fact, a close analogy to the case of the rabbits in which the development of initial lesions was hindered. We need something more than the arsenobenzol class of preparation for the eradication of syphilis, or shall we say for the protection of the patient against the activity of the spirochæte, and herein is a rôle for the antispriochætal remedies of the other class represented in working practice by mercury and bismuth.

Mercury has long been known as a remedy which acts slowly but more or less persistently. As judged

by animal experiments, its spirochæticidal action is feeble in relation to its toxic, and, personally, I have always believed that in most cases treated by mercury the disease has just simmered on. The patient may have been protected against the development of granulomata, but has been rid of his infection. An advantage, however, of mercury, as also of bismuth, is that it can be given in such a way that it remains in the body constantly, restraining the action of the spirochætes, or perhaps restraining the tissues from kicking against them. Mercury has the advantage over bismuth that it can be given otherwise than by injection, as for example if one wishes to continue treatment by mouth, but when injection treatment is indicated I think that the preference will be given to bismuth because this is tolerated far better.

Bismuth.—According to the experiments of Levaditi and other workers, bismuth is much more actively spirochæticidal than mercury. Levaditi and a few others consider that bismuth is superior to the arsenobenzol preparations, but most workers rank it as a substitute for mercury. Certainly, by giving the more soluble preparations of bismuth, one can cause *S. pallida* to disappear quickly from the secretion of surface lesions, but there are disadvantages in the use of such preparations from the point of view of toxic effects, and unless there are contra-indications to the use of arsenobenzol, I prefer, like most workers, to give bismuth in such a form and in such a way as to ensure a steady absorption which on the one hand is not so rapid as to upset the mouth and kidneys, and on the other, not so slow that successive injections build up a large depôt at the sites of injection. Too large a depôt might become dangerous if the absorptive capacity of the tissues suddenly became greater as happened occasionally in the bismuth treatment of war wounds. The experiments of Levaditi and colleagues have shown that the antisiphilitic effect of bismuth is exercised when the tissues, apart from those at the sites of the injections, have taken up a certain minimal amount of the metal proportional to their weight. Later Lomholt found that a watery suspension of bismuth oxychloride was absorbed with satisfactory evenness. Engelhardt's analyses of urine from patients after administration of various preparations of bismuth show that alia that paraffin is worse than oil as a vehicle of suspension and that the absorption of the tartro-bismuthate of potassium and Sum (trepol) suspended in oil is very slow. This seems to be confirmed by Levaditi's finding that the administration of the maximum tolerated dose of trepol to a rabbit protects it against syphilitic infection for 152 days. Engelhardt's work generally showed that the most evenly absorbed of the preparations which he tested was a solution of bismuth naphthenate in oil which is sold as Embial. I have very little experience of this preparation—certainly not enough to enable me to compare it with others. Amongst other preparations which he investigated the subsalicylate in oil proved satisfactory.

My own experience is largely confined to bismuth in fine subdivision, the oxychloride suspended in glucose solution, the salicylate suspended in oil, and iodo-bismuthate of quinine. Generally I prefer a compound to the metal in fine subdivision, though I cannot support the preference by any analyses showing rates of absorption. An early case which was intolerant of "914" had received a number of injections of bismuth metal and should theoretically have been thoroughly under its influence. He developed paralysis of the sixth cranial nerve, and I began to doubt the absorption. It seems probable that, whatever preparation is used, it is reduced to the same state, a compound of the metal with albumin—i.e., Levaditi's bismoxyl—before it is taken into the circulation, so that one might imagine it better to feed bismuth to the tissues in the form of the metal itself just as is often done in giving mercurial injections. On the other hand, it seems probable that the metal may be more easily absorbed when in the nascent state newly removed from a compound, and I think there is support for this in the fact that the soluble compounds

of bismuth are far more rapidly absorbed than is the metal in fine subdivision. The iodo-bismuthate of quinine has the disadvantage of a low bismuth content, about 20 per cent., so that the individual injections have to be bulky to ensure the absorption of a sufficiency of bismuth, and I prefer the oxychloride or the salicylate. Of either the salicylate or the oxychloride I give 4 g. (totaling 2 to 3.2 g. bismuth metal) in a course of ten injections.

Concurrent versus Alternate Courses.

A question of considerable importance is whether one should give the bismuth at the same time as the arsenobenzol or give first a course of arsenobenzol injections and then one of bismuth. Firmly (I might say dogmatically) I am convinced that it is a mistake in an early case of syphilis to withhold the bismuth or the mercury until the end of the first course. Earlier in this article I pointed out that patients treated by arsenobenzol preparations alone tend more to suffer from syphilitic neuro-recurrences, and when I compare my experience in this matter with that of clinicians who give only arsenobenzol preparations at first, I am certain that the plan of giving the two remedies concurrently protects the central nervous system.

The next question is the amount of treatment which should be given to an early case of syphilis. In the analysis of cases treated at St. Thomas's Hospital, which was published some time ago by the Medical Research Council, I showed that some seemed to have been cured by an amount of treatment which nobody would agree was sufficient for the average case. On the other hand, even with sero-negative primary cases less than three full courses of "914" (5 to 6 g. in each) and bismuth or mercury, with intervals of two and three months between courses, left us with a percentage of relapses. With cases of sero-positive primary and of early secondary syphilis in the categories which had received even three courses there were 10 per cent. of relapses in my series, and I think that for cases which have reached the stage of positive serum reactions it will be necessary to prescribe more than three such courses as we give at St. Thomas's. I have tried the effect of spacing out the injections of "914" at much longer intervals than is customary at present, filling up the intervening weeks with injections of bismuth. The immediate results seem to have been as good as those of the course in which we gave ten injections of "914" in 13 weeks, but I am not yet able to speak as to permanence of effect.

I had hoped to prevent toxic effects of "914" by dissolving the remedy in 10 per cent. sodium thio-sulphate, but, although dermatoses were reduced, the incidence of jaundice remained the same. We are now dissolving the "914" in 20 c.cm. of 40 per cent. of glucose, and I think that it has had a good effect in reducing the incidence of jaundice.

Summary.

To summarise my views on the treatment of early syphilis I would say that:

(a) The results of treatment before the serum reactions have become positive are far superior to those in later cases even though the secondary rashes have not appeared.

(b) The concurrent use of bismuth (or mercury) with "914" is likely to result in a minimum of relapse in the central nervous system—far less than when a course of "914" is followed by one of bismuth or mercury.

(c) However early the treatment is commenced three full courses should be given each totalling 5 to 6 g. "914" and 2 to 3 g. bismuth and lasting 10 to 13 weeks. If treatment commenced after the serum reactions had become positive, I would now prescribe more than three such courses.

TREATMENT OF LATER CASES.

Tertiary manifestations affecting the skin, mucous membranes, bones, muscles &c., require little mention because they usually yield to such treatment as is given to early cases. In late affections of the

cardiovascular system I am a believer in the use of arsenobenzol preparations. Some workers consider these preparations are contra-indicated in syphilitic myocarditis, and I admit that one has to proceed carefully, but with doses of 0.2 to 0.3 g. sulpharsenobenzol given twice weekly, concurrently with bismuth injections, I have seen most beneficial effects. In tertiary disease of the liver I think arsenobenzol treatment is contra-indicated and prefer to rely on bismuth and iodides. In syphilis of the meninges after a cautious start lest a Herxheimer reaction should prove serious, I think one should push both arsenical and bismuth preparations to the limit of tolerance and I have seen only good from following this line. In *tabes* I prefer sulpharsenobenzol intramuscularly in conjunction with bismuth, or silver-salvarsan intravenously, and here also when practicable adopt the plan of giving injections twice weekly. Our results with trypanamide have been rather mixed, but in both *tabes* and general paresis, like other workers, I have seen great benefit from malarial treatment.

I have said little about the use of iodides. Their rôle appears to be to stimulate the tissues to remove infiltrates, and for this purpose they seem to be indicated in early as well as in late stages. The work by Brown and Pearce already mentioned indicates also that iodides assist the defensive reactions and this is another reason for employing them. In later cases, and especially in *tabes*, I believe in pushing iodides to the limits of tolerance.

Lastly, I should like to emphasise the importance of measures designed to improve the patient's metabolism. We depend for spirocheticidal effect on derivatives of our remedies and patients differ greatly in the use they make of what we put into them as we can surmise from the fact that while some patients have been cured by single doses of "606," others have proved most intractable. We know too little about the processes which make for a good response to treatment, but one can well believe that the patient who is kept physiologically fit will afford us a better result than a sluggish or one we depress unduly by pursuing a rigid programme in spite of obvious signs of intolerance. Altogether, therefore, I would give plenty of treatment but only on condition that my patient is not unduly depressed by it. If he is, perhaps a holiday in good surroundings will do more for him than many injections.

L. W. HARRISON, F.R.C.P. Edin.,

Director, V.D. Department, St. Thomas's Hospital.

MEMORIAL TO A PHYSICIAN.—A tablet to the memory of the late Dr. J. T. Dunlop, who was honorary physician to the Newcastle Hospital for Diseases of the Skin, has been placed in the entrance hall of the building.

BIRMINGHAM HOSPITALS.—Birmingham General Hospital closed last year with a debit balance of £26,000; the Queen's Hospital had a deficit of £14,500. The dietetic clinic at the General Hospital "has gained in importance," and further developments have been made in the treatment of cancer by radium. The institution has been selected as a centre for radium treatment and research. Motor accidents are costing between £10,000 and £15,000 a year, and at the annual meeting it was finally decided so to alter the rules as to enable the victims of such accidents to be asked to pay for treatment. There were over 7000 in- and nearly 68,000 out-patients. The experiment of setting aside 30 beds for paying patients has proved an entire success from all points of view.—At the Queen's Hospital the average daily cost of in-patients (6004, an increase of 418) was 8s. 7d. and of each bed per year £156 14s. 3d. The report of the hospital work of the Birmingham Board of Guardians for the year ended on March 31st, 1929, shows that at the Dudley Road and Selly Oak Hospitals and the Lordwood Nursery, 22,958 in-patients were treated.—At the annual meeting of the Midland Nerve Hospital it was stated that the institution had reached saturation point as regards in-patients, and that "no other hospital out of London is treating nerve diseases as they are being treated" at that hospital. There were 63,000 out-patient attendances last year. An operating theatre and some isolation wards are to be added.

Special Articles.

A NOTE ON THE HEALTH OF THE CONSUMPTIVE WORKER UNDER SETTLEMENT CONDITIONS.

By E. L. SANDILAND, M.B. LOND., D.P.H.,
MEDICAL SUPERINTENDENT, EAST LANCASHIRE TUBERCULOSIS
COLONY.

In view of the interest taken in this subject by many tuberculosis officers and other workers in tuberculosis some observations after six years' experience of a small settlement may be worthy of note. The East Lancashire Tuberculosis Colony and Sanatorium was established at Barrowmore Hall, near Chester, in 1921 for concurrent treatment and training of 70 cases. In 1924 the accommodation was extended to 112 beds, and sanatorium cases were admitted for treatment. In 1928 the accommodation was extended to 120 cases. Twelve cottages have been built for married settlers and a hostel for ten single settlers.

Sickness Among Settlers.

The first colonist was settled in 1922, and he is still in the settlement. Since that date 33 other men have been made settlers. Of these 34 settlers, three advanced cases have died and five have left the settlement, in the majority of cases to take up work elsewhere. There are now 26 settlers in all on the estate. The length of time these men have been settled and the periods of sickness up to Jan. 1st, 1930, are as given in Table I.

TABLE I.

Time colonised.	No. of men.	Total period of sickness for each group.
7 to 8 years. . . .	1	6 weeks.
5 " 6 " " " " "	9	60 "
4 " 5 " " " " "	2	3 "
3 " 4 " " " " "	5	20 "
2 " 3 " " " " "	4	15 "
1 " 2 " " " " "	1	nil
Up to 1 year . . .	4	nil
—	26 men.	104 weeks.

The total time of settlement of these 26 men amounts to 93 years and the total period of sickness from tuberculosis amounts to two years.

Types of Industry.

The industries carried on are these:—

(1) *Woodwork*.—in which the majority of the men are employed. The heavy work is done by machinery to relieve the workers and increase the output. Some of the settlers, however, have a surprising capacity and desire for the heavier work. One case of artificial pneumothorax, which was at one time double, has given the medical staff some anxious moments on account of his zest for work.

(2) *Upholstery*.—One worker employed in this industry had a severe attack of pneumococcal lobar pneumonia and recovered; this attack apparently suspended the activity of the tubercle bacillus for some time. The dust inseparable from the teasing out of old stuffings is avoided by the use of a well-protected carding machine which has a fan and ducting to remove the dust outside the shop.

(3) *Boot Repairs*.—A finishing machine relieves the heavier work in this department.

(4) *Decorating*.—The work done by these men is almost entirely internal painting.

(5) *Poultry Farm*.—The work on a large poultry farm is at times rather heavy, especially as the work must continue over the week-ends.

(6) *Gardening*.—The settlers do no heavy digging. Other settlers are employed on clerical work, one as a porter and one as a lorry driver.

Extent of Disease.

Of these 26 men, 12 have had positive sputum and 14 have negative or no sputum at all. The anatomical extent of the disease compared with the time of sickness is shown in Table II.

TABLE II.

	Diseased lung.				
	1 lo.	2 lo.	3 lo.	4 lo.	—
T.B. minus cases	2	8	2	2	14 men.
Total time of sickness in weeks . . .	0	15	5	3	23 wks.
T.B. plus cases	0	0	6	6	12 men.
Total time of sickness in weeks . . .	0	0	17	64	81 wks.

lo = lobes.

Working Hours and Absenteeism.

The total number of possible hours which these 26 men could have worked is 182,521 hours, and the total hours of work lost by these men through sickness due to tuberculosis was 4066. This represents 2.2 per cent., which would compare favourably with most communities. During the year January, 1929, to January, 1930, the carpentry department was employing 13 settlers. The total possible hours which these men could have worked during the year was 21,146. There were lost from sickness due to tuberculosis 1616 hours (7.2 per cent.), and of this number 1298 hours, or 80 per cent., were lost by one man, who is still under treatment.

Nine of the settlers have gained weight, the average gain being 7½ lb.; 17 of the 26 have lost weight, the average loss being 5½ lb.; 22 are working seven hours per day, and the remaining 4 eight hours per day. These men on eight hours per day are working under the same sheltered conditions as the men on less hours, and are not comparable with men working eight hours per day in the outside world. They are never pressed to work to their utmost capacity, not are they in competition with robust healthy workers. All the men are under constant medical supervision, and any failure in health is soon noted and treated, and, if necessary, the man's work is made easier for the time being; in this way long breakdowns have been avoided.

Should a man break down for a short period he is immediately admitted to the sanatorium and given the benefit of institutional routine and nursing, and his family is assisted, if necessary, from a fund provided for that purpose. This immediate institutional treatment, even for quite a short period, is of the utmost value in preventing serious relapses.

The goods for sale are being standardised as much as possible so that repetition work can be introduced. This is found advantageous from the point of view of the health of the worker, as well as for commercial reasons. Certain repetition work is suitable for unskilled sanatorium patients as part of their occupational therapy.

Discharged Settlers.

The industrial history of the five men who left the settlement is as follows:—

1. Married. Sputum-negative case; two lobes involved. Was a settler for two years as caretaker at hostel, where he worked seven hours per day. He had no breakdown.

2. Single. Sputum-negative case; two lobes involved. Was a settler four years. Worked in firelighter department seven hours per day for two years; afterwards drove Ford van for two years. He had no breakdown.

3. Single. Sputum-negative case; two lobes involved. Was a settler for three years. Worked seven hours per day in piggery for one year. When piggeries were closed down was employed in firelighter department for seven hours per day for two years. He had no breakdown.

4. Single. Sputum-positive case; three lobes involved. Was a settler for 18 months. Worked five hours per day in boot-repairing department. Broke down for three months and decided to return to his people. This man's habits were not conducive to good health.

5. Single. Sputum-negative case; two lobes involved. Was a settler for 16 months. Worked seven hours per day in carpenter's shop. Decided to return to his people. Had no breakdown.

Fatal Cases.

The three deaths among the settlers occurred in 1927. All three were rather advanced cases; two had positive sputum and one had a negative sputum. They all lasted 18 months as settlers before their final breakdown. Two had never worked in the settlement for more than five hours per day, and the third worked seven hours per day. They all had short relapses from a week to a month before their final breakdown. These cases were all rather hopeless from the first, but they were made happier by being part-time employed during the last months of their lives. They lasted longer and at less expense to the community than they would have done in the outside world, and were not a source of danger to the general public.

INVESTIGATIONS ON

DIET IN HEALTH AND DISEASE.

RESEARCH SUBSIDISED BY THE MEDICAL RESEARCH COUNCIL.

A CONSIDERABLE proportion of the research work now in progress under the auspices of the Medical Research Council is concerned with the relation of variations in diet to the maintenance of health or the incidence of disease. The discovery of vitamins has enmeshed dietetic experts in a maze which grows increasingly complex as the number of known accessory food factors increases. But apart from these, other dietetic questions—for example, those of sugar hunger and sugar tolerance, of the desirability of pushing or withholding protein in the diet of patients with kidney lesions, of fat indigestion, especially in children—are assuming greater and more precise importance in clinical medicine than ever before. It is, therefore, appropriate to call attention in this concluding notice of the Medical Research Council's annual report for 1928-29 to those researches carried on in all parts of Great Britain which are directly or indirectly concerned with diet.

Relation of Diet to Infection.

At Sheffield Prof. E. Mellanby and Dr. H. N. Green have been investigating the relationship of diet to infection.

It was found that when rats were fed on a diet devoid of vitamin A they almost invariably died with septic infections. When vitamin A was present in the food these infections did not develop, while the administration of foodstuffs rich in vitamin A to animals already infected often brought about complete recovery. Vitamin D did not have this preventive action; indeed it often appeared, if given unbalanced, to hasten illness in young animals, probably because it brought about more rapid growth and a quicker exhaustion of the stores of vitamin A already present in the body.

Consideration of the average diet consumed by the population under modern conditions suggested that similar influences might play some part in human resistance to bacterial infection. As a clinical study it was decided to investigate the effect of vitamin A preparations in puerperal septicæmia. This disease was selected because its case mortality is so great that with comparatively few tests a rapid inquiry could be made into the truth of the hypothesis. Although the number of cases investigated is still small, the results suggest that a definite increase of resistance to this disease is given by intensive vitamin A therapy.

So far as puerperal sepsis is concerned, the results tend to emphasise the importance of the condition of the mother before infection rather than the part played by the midwife and doctor, a view which is on the whole opposed to the present trend of thought. If, for instance, it is possible by dietetic therapy to cure cases of puerperal septicæmia, it ought to be even easier to prevent this and other forms of sepsis by proper feeding of the mother during the puerperium. To obtain evidence on this point, an investigation has been begun at the out-patient department of the Jessop Hospital, Sheffield, with the assistance of Dr. Doris Pindar. The small amount of evidence so far obtained supports this hypothesis.

Dr. Green and Prof. Mellanby are also conducting animal experiments to gain insight into the mode of action of vitamin A in septic conditions, and to find the part played by other food elements in the resistance of the body to infection. Further observations on a larger scale are contemplated to decide whether the same influences apply to other infections such as pneumonia, tuberculosis, and rheumatic fever.

Dr. W. M. Roberts has determined the effects of oils on secretion and motility of the stomach wall.

Nutritional Disorders in Infants and Young Children.

Dr. Stanley Graham and Dr. Noah Morris, working in Glasgow, have been investigating the disturbances of acid-base equilibrium in infancy and childhood, with special reference to congenital hypertrophic pyloric stenosis and cyclical vomiting. Dr. Morris and Dr. Olive Macrae are studying the mineral and fat metabolism and the variations produced by modifications of dietary in colic disease; while at Birmingham, Dr. Leonard Parsons, with Dr. S. H. Edgar, Miss E. M. Hickmans, and Miss M. S. Esselmont, is investigating the biochemistry of this and other diseases in children. The effects of variation in the diet on a group of children in the convalescent stage of acute rheumatism has also been studied.

Dr. Helen Mackay and Miss L. Goodfellow (London) have shown that the anaemia common in breast-fed infants is a nutritional anaemia like that already studied in artificially-fed infants. It appears that resistance to infection can be increased by the regular administration of a suitable iron salt and by the consequent prevention of this type of nutritional anaemia.

As a result of work at Guy's Hospital and elsewhere Dr. A. A. Osman has defined a condition of debility in children which is associated with acidosis, and is a milder degree of the syndrome known as "cyclical vomiting." This may be quickly overcome by giving sugar.

Studies of Growth.

At University College, London, Dr. H. A. Harris has been unable to substantiate the claims made for the superiority of irradiated ergosterol over cod-liver oil in the treatment of rickets. He holds that vitamin D can influence calcification in cartilage, but that true osteogenesis is determined by vitamin A alone. A study of susceptibility to perversions of growth has been made in the child and in the rat. The results indicate that all dietetic experiments on rats of more than 30 days old at the beginning of the experiment are unreliable, because by the fifth week the rat has ceased to grow at such a rate as to permit of the onset of acute rickets.

National Dietsaries.

Dietary studies are being made at Glasgow by Prof. E. P. Cathart, assisted by Mrs. A. M. T. Murray and Miss M. Shanks. These studies consist in the analysis over a suitable period of the diets in use in a series of typical households in various towns. Data from St. Andrews have now been completely analysed, and the results obtained are definite and informative. Good progress has also been made with the analyses of Cardiff and Reading diets, and it is hoped the

study will be completed by the investigation of one or more towns in the northern industrial area, probably in Lancashire or Yorkshire. At King's College Hospital, London, Dr. R. A. McCance, Dr. R. D. Lawrence, and Mr. H. L. Shipp have completed an analysis of carbohydrate foods, differentiating those available and unavailable for the purposes of metabolism, and have begun a similar investigation into the nutritional value of other cooked foods, especially meat and fish.

Trials of the relative values of brown and white bread have been made with rats by Prof. V. H. Mottram and Dr. G. A. Hartwell, and the results have been published in our columns. Dr. Hartwell has continued her work on synthetic diets.

Iodine in Foodstuffs.

In Aberdeen Dr. J. B. Orr, with the assistance of Miss G. L. Stuart and Mr. N. L. McPherson, has continued work on the relationship of iodine in foodstuffs to the distribution of goitre, further samples having been collected from selected English and Scottish areas. A review of existing information on iodine in nutrition, by Dr. Orr and Dr. Isabella Leitch, has been published.

Diet in Tetany.

At St. Bartholomew's Hospital Dr. G. C. Linder and Dr. C. F. Harris have investigated the influence of parathyroid extract, thyroid extract, and calcium salts in cases of tetany after operations on the thyroid gland. In tetany associated with steatorrhœa, the influence of fat in the diet and of irradiated ergosterol have been studied, and a preliminary report has been made. Satisfactory therapeutic results have been obtained.

Antiscorbutic Activity.

The Council have again received a grant from the Empire Marketing Board for the investigation of the vitamin content of various Empire food substances. The work is being done by Dr. S. S. Zilva at the Lister Institute with five assistants.

Continuing the chemical investigation of the antiscorbutic factor in lemon-juice, Dr. Zilva has studied the causes of the spontaneous inactivation of the vitamin.

Experiments on the relation to maturity of the antiscorbutic activity of citrus fruits have been begun. A group of orange trees near Jaffa has been set aside for this purpose. Consignments of this uniform yield were sent periodically during the season and examined chemically and biologically. Details of the history of the trees, such as age of stock, budding, soil, cultural treatment, climate, and conditions of picking, are known. Grape fruit from British Honduras has been similarly collected.

Dr. L. J. Harris, with Dr. E. W. Fish, is studying the effects upon tooth-structure of long-continued slight shortage of vitamin C.

The Fat-soluble Vitamins.

The inquiry into the A and D vitamin contents of Dominion dairy products, and the influence upon them of environment, has been extended to Australian butters.

With Captain Golding, of the National Institute for Research in Dairying, Reading, a study of factors causing destruction of the fat-soluble vitamins in milk has been begun by Dr. Zilva. The influence of a diet deficient in fat-soluble vitamin on the development of sensitivity to tuberculin in rats infected with *B. tuberculosis*, is being studied with Dr. H. Schütze.

Miss E. M. Hume, with Miss Henderson Smith, has studied the calcification of the bones of rats irradiated with ultra-violet light and kept on a diet as free as possible from ergosterol. At present it does not seem that calcification is limited by the absence of ergosterol from the diet.

Prof. J. C. Drummond, at University College, London, from a chemical examination of the vitamin A fraction of certain liver oils, concludes that this vitamin must form a very minute proportion

of even the most active concentrates that have as yet been prepared. With Prof. Heilbron, of Liverpool, feeding tests are being made by Prof. Drummond with synthetic preparations which might be suspected of being related closely to vitamin A, and might exhibit its activities.

In the new Nutritional Laboratory at the Field Laboratories, Cambridge, Dr. L. J. Harris and Dr. T. Moore have studied the effects of giving massive doses of irradiated ergosterol. Evidence has been got that the ill-effects are due to overdosage with vitamin D itself, and not to any impurities produced during the irradiation.

With Dr. C. P. Stewart, of Edinburgh, Dr. Harris has found that experimental hypervitaminosis D in rabbits or rats is shown by raised blood phosphate or blood calcium, or both, and this state is in contrast with that observed in avitaminosis D (rickets). Mr. Innes, collaborating here, finds that the microscopic changes are the opposite of those seen in rickets.

Dr. Moore has confirmed the results of Swedish workers, who found that the pigment carotene, even after many recrystallisations, invariably has intense vitamin A activity when given in minute doses under defined dietary conditions.

Carotene and the classical vitamin A of cod-liver oil are not identical; but carotene may be a precursor of the classical vitamin A, and capable of conversion into it in vivo.

The carrot has been found to be a much richer source of vitamin A activity than was hitherto supposed. On a basis of dry weight the carrot root must approach cod-liver oil activity; and on account of its ready accessibility and, cheapness this fact may have economic importance. Dr. Moore has also tested carotene for vitamin D, with quite negative results. This pigment may be a useful means for giving vitamin A, in nutritional experiments, without the vitamin D which so often accompanies it in foods.

The Minimum Nutritive Requirements of the Mammal.

Experiments have been made during the year at University College with the object of deciding what are the minimum nutritive requirements of the mammalian organism, as represented by the rat. The fact that fats are not essential constituents of the diet has been confirmed. Fat in the diet may change the demands of the organism for one or all components of the vitamin B complex, and failure to recognise this has led other workers to attribute an essential rôle to the fats as such.

Two voluntary workers, Miss F. J. Hargreaves, of Toronto, and Miss Clay, have joined in studies of the relation of animal appetite to vitamin requirement, while Dr. A. N. Drury, with Dr. C. W. Carter, of Oxford, has been investigating a cardiac irregularity noticed in pigeons fed upon polished rice.

The Water-soluble B Vitamins.

At the Lister Institute Dr. Margaret Fixsen, working under Dr. Harriette Chick, is investigating the part played in the metabolism of nitrogen by the water-soluble B vitamins.

It is probable that the presence or absence in the diet of the recently discovered heat-stable vitamin B₁₂ has influenced the results obtained for the "biological values" of various proteins. Some of these biological values are being redetermined by experiments in which the animals are supplied with an adequate ration of all vitamins at present known.

At Oxford Miss Vera Reader and Mr. H. W. Kinnersley have been working with personal grants on the yeast vitamin B₁ (torulin).

Mr. Kinnersley and Prof. Peters have much simplified their methods of obtaining the most active torulin concentrates, so as to work upon a large scale. By studying the changes in the brains of birds with lack of vitamin B₁, Mr. Kinnersley and Prof. Peters conclude that this want interferes with the oxidative removal of lactic acid in muscular activity, and agree that torulin is specifically concerned with carbohydrate changes in the body.

Miss Reader has again worked upon the growth-promoting activity of the purer torulin concentrates, and she has found a third factor in this very complex substance. This factor, B₃, is thermolabile, and has a curative effect on pellagra. Continuing to investigate the abnormally enhanced effect produced by impure extracts of torulin, Miss Reader has found that the addition of mannitol to a pure extract specifically imitates this abnormality. The separation of the two substances which together appear to be responsible for the physiological effects of concentrates of vitamin B₃, is being made on a large scale (so as to get quantities enough for adequate purification) by Dr. B. C. Guha and Dr. F. L. Pyman.

Miss R. Stern, working at the National Hospital, under the direction of Dr. J. G. Greenfield, has completed her study of the effects of diets deficient in vitamins B₁ and B₂ on the nervous system.

Influence of Diet on Dental Disease.

Mrs. M. Mellanby, at Sheffield, has continued her work on the relations between the original structure of the periodontal tissues and their liability to infection, and between diet and liability to infection under normal and abnormal conditions of structure, and has also, with Dr. C. Lee Pattison, obtained confirmatory evidence of the healing effects of vitamin D upon active dental caries in children. She is supervising an inquiry at Birmingham into the influence of diet on the development and extension of caries in the teeth of children.

Dr. J. R. Marrack (London Hospital) is investigating the influence of an increased intake of vitamin D, and of added calcium lactate and cod-liver oil, on the calcium content of the saliva.

At Sheffield Dr. C. G. Imrie and Miss M. Hirst have been observing the effects of diet free from creatine, and of the oral administration of creatine were also observed. Other studies have been made of the creatine and phosphorus in the muscles and in the blood and urine after giving creatine in food.

Physiology of Digestion.

Under the direction of Dr. G. A. Harrison at St Bartholomew's Hospital, Miss F. K. Herbert is studying the range of variation of the sugar tolerance in normal persons. Dr. R. J. Brocklehurst, at University College, London, has been investigating the gastric secretory response to food in animals.

Liver in Pernicious Anæmia.

At Edinburgh Dr. Stanley Davidson with Prof. Gulland have made further studies in confirmation of the work of Minot and Murphy showing the efficacy of liver treatment in pernicious anæmia. Examinations of the intestinal bacteria in this disease have shown quantitative increase above the normal, but no constant qualitative abnormality; no correlation has been found between increase of intestinal bacteria and the clinical condition.

Conclusion.

The Council announce that the trustees of the late Sir William Dunn have given £6000 for the erection of a nutritional laboratory upon a site at the Field Laboratories, Cambridge, provided by the University. This laboratory is so placed and designed as to give the most hopeful conditions for investigation in this increasingly important field of medicine. The research work here will be brought into close relations on the one side with the University departments for the primary medical sciences and on the other with the nutritional work being done in the interests of agriculture and veterinary medicine.

TORBAY HOSPITAL.—The report for the first complete year of the new hospital states that 1668 in-patients were admitted, and that there were 4265 new out-patients. The average daily cost for in-patients (146 beds) was 7s. 7d.; the average period of residence was 24·21 days.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

The Question of Reciprocity.

THE recognition of Indian Medical degrees by the British Medical Council is now in imminent danger of being withdrawn. Following the Government's failure to form an All-India Medical Council the General Medical Council was to have been pacified and the gap to have been filled by the appointment of a commissioner of medical qualifications in India. But the Legislative Assembly have refused to make this appointment. The attitude taken by the medical press here is that the General Medical Council are being dictatorial and that any attempt on the part of India to meet their wishes would be undignified. They demand that, if recognition of Indian degrees is refused, India should refuse to recognise British degrees. I understand that the question of an appointment of a Commissioner is to be dropped but that the Government is determined on the formation of an All-India Medical Council in the near future.

Proposed Central Research Institute.

The scheme for the establishment of a new Central Research Institute has received a severe set-back. The Standing Finance Committee of the Central Government have passed the annual grant to the Indian Research Fund Association only on condition that the whole Dehra Dun scheme is reconsidered by a committee appointed for the purpose. Opposition to this scheme has come from an entirely new quarter. The money which has been earmarked for the last ten years for the building of this institution has now come to be looked upon as part of the capital of the Indian Research Fund Association, and expenditure from this capital sum will naturally curtail the research programme of the Association; the scheme was, therefore, not popular amongst research workers in India. It has always been considered by a section of the research workers that the new Institute should be located within easy reach of clinical material in one of the large Presidency towns. Some of the opposition to the localisation of the Institute at Dehra Dun was overcome when it was pointed out that this Institute would be devoted mainly to basic research and that, as there was already a suitable building at Dehra Dun which could be obtained without cost, the only expenditure would be a comparatively small sum for making certain alterations and additions. Eyebrows were lifted slightly when it was stated that this "small sum" would amount to six lakhs of rupees, and considerable sympathy with the scheme was lost when it was rumoured that the original sum mentioned was a gross underestimate and that the total expenditure on bricks and mortar alone would be more than twice this sum. Research workers feel that they have never been taken into the confidence of the Government over this scheme. The Fletcher Committee report was not circulated freely until about a year after its publication, and nothing about the additional expenditure at Dehra Dun was told to the All-India Research Workers Conference held at Calcutta last December. The need for a central Institute is admitted and most research workers are reconciled to its localisation at Dehra Dun, provided the grants which the provincial institutions—such as the Haffkine Institute in Bombay, the School of Tropical Medicine in Calcutta, and the King Institute in Madras where the more practical research problems can be tackled—have received from the Indian Research Fund Association during the last few years are not cut. Present opposition appears to be of a political nature.

Standardisation of Drugs.

At present there is no legislation which makes it necessary for drugs offered for sale in India to be

of any given standard or even to be what they purport to be, provided they are comparatively harmless. The matter has recently been taken up by the Central Government and a provision of Rs.1,10,000 has been made for the appointment of a committee to inquire into the question of importation, manufacture, and sale of medicines and drugs of impure quality or defective strength. I understand that the inquiry will be limited to drugs in common use in scientific medicine, and will not include those used in the so-called indigenous systems of medicine.

Recruitment for the I.M.S.

When this question came up before the Legislative Assembly in January one speaker urged that the time had now come for the revival of the entrance examination; the examination should, he thought, be held in India. This suggestion did not receive much support, but an amendment that the competitive examination should be revived and should be held in India and in England simultaneously received the support of the European group in the Assembly. The Government spokesman pointed out that before the war, when recruitment was solely by examination, the proportion of European to Indian admissions was 7 to 1, but that at present it was 2 to 1. He said that this proportion was not final and could be altered if a *prima facie* case for alteration were made out, but he considered that the resolution, in so far as it involved an immediate radical alteration in the organisation of the service, was premature. Eventually a resolution following the lines of the amendment was carried without a division.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Proposed Reform of the Vaccination Laws.

THE German Federal Health Council in their last meeting have recommended the Government to modify compulsory vaccination. The proposals are that: (1) conscientious objection of the parents should be considered; (2) the number of children to be vaccinated by any particular medical officer should not be too large, in order to allow him to examine them thoroughly to ascertain their constitutional fitness for vaccination; (3) forcible prosecutions by the police to enforce vaccination should be altogether abolished. If a vaccinated child has been injured by vaccination the State should be liable to pay damages. The decision to make these recommendations was taken on the authority of Prof. Schlossmann, the well-known specialist for children's diseases in Düsseldorf. He stated that 28 cases of post-vaccinal encephalitis were recorded in 1928—a number very small compared with the two and a half millions of children vaccinated in the same year. He was also of opinion that without vaccination the number of cases of encephalitis as a sequel to small-pox would certainly be greater. But post-vaccinal encephalitis has afflicted healthy children and has thus caused much sorrow to their parents. Cow-pox is not a local disease as was formerly believed. He described himself an absolute adherent of vaccination, but without coercion.

Notification of Diphtheria.

A medical man was lately prosecuted because he had not notified a case of diphtheria in a child who eventually died from the disease. He pleaded that he had not been certain that the child suffered from genuine diphtheria and had thus not felt obliged to notify the case. The court found him not guilty. According to the provisions of the Infectious Diseases Act (Prussia), a case of diphtheria, measles, or scarlet fever must be notified by the medical attendant within 24 hours of ascertaining the nature of the disease. If the doctor was not aware that the patient was suffering from an infectious disease he

cannot be punished. The court had not to decide whether by better care he might have arrived at a right diagnosis. According to the Federal Act concerning the prevention of epidemics, including small-pox, plague, cholera, typhus, and other diseases of an extraordinarily grave and infectious character, medical men have to notify at once even suspected cases, and a medical man omitting such notification would be liable to prosecution. But that does not apply to diphtheria where notification is compulsory only after the diagnosis has been made.

Surgical Complications of Dengue Fever.

Dr. Toole reports in the *Archiv für Klinische Chirurgie* on surgical complications which occurred during the great epidemic of dengue fever in Greece. The complications affected 2000 of 650,000 patients and happened during the course of the disease or during convalescence. Among them were infectious processes produced by staphylococci and sometimes by streptococci, furunculosis, phlegmons, and parotitis. They were due partly to the fact that the resistance of the patients was diminished by the illness, but partly to external circumstances. Thus it happened that, owing to the great pressure on the medical and nursing staff, in some cases injections were not made quite aseptically. Dr. Toole does not connect dengue fever with inflammation.

The Methods of Valentin Zeileis.

The activities of Valentin Zeileis, recounted by your Austrian correspondent, have aroused interest here, for Gallsbach, where he has acquired an enormous practice, lies near the German frontier. At a recent meeting of the Berlin Medical Society Prof. Lazarus, who has visited Gallsbach, gave an account of his methods. According to him, Zeileis brings a Geissler tube near a patient, telling him that, when the tube is near an affected organ, the rays within the tube become more brilliant and that he is thus able to diagnose the nature of the disease. For every disease he applies the same treatment—high-frequency currents, radium and Röntgen rays, and light treatment, in that order. He treats 100 patients simultaneously in a great hall; they come three times a day for at least three weeks, sometimes for several months. If he confined his attention to hysterical patients, who are influenced by the flash of the rays, the smell of ozone, and by their own faith no harm would be done, but he and his school pretend to cure organic troubles too, and this keeps genuine patients from consulting medical men. Prof. Lazarus has reported various catastrophes that have followed this treatment. The position is complicated by the fact that Zeileis by his mass methods is able to attend daily from 1000 to 2000 patients. The whole neighbourhood thus profits from his clinic. Several hotels have been built in the small country town of Gallsbach and motor-buses are in operation. The mayor and the peasants resent any doubts thrown on the efficacy of the treatment because of the prosperity brought to the town thereby. Prof. Lazarus's report has been published not only by the medical journals, but by the great Berlin daily newspapers too; its effect, however, was contrary to that expected by its author. The report has acted as propaganda; a Zeileis institute has been opened in Berlin, where the methods of the master are applied, and Zeileis has threatened to bring an action for slander against Prof. Lazarus. The Austrian authorities have left him undisturbed, possibly for financial reasons, and possibly because he has been covered by the name of his son who is a qualified medical man. He has, moreover, declared that if he is prosecuted he will go over the neighbouring Bavarian frontier and settle there, since unqualified practice is not illegal in Germany. There is obviously little prospect of success for the struggle against unqualified practice while the public prefers mystic proceedings to scientific methods.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

For Public Health in France.

Two creations have just been made in France for public health. One is the *Ministère de la Santé Publique*, the other is the *Parti Social de la Santé*

Dr. A. Leitch, and Dr. W. Cramer. The chairman was Prof. Roussy, and the secretary Prof. Declman (Amsterdam). There were also present Drs. Blumenthal (Berlin), Bierich (Hamburg), Borrel (Strasbourg), Lipschütz (Vienna), Maisin (Louvain), Teutschländer (Berlin), de Vries and Waterman (Amsterdam), Askanazy (Geneva), Dustin (Brussels), Finkel (Liège), Fichera (Milan), Moller (Copenhagen), and Pentimalli (Naples).

Central building of the Institute for Cancer Research of the Paris Faculty of Medicine at Villejuif.

Publique. Of the former there is little to say, for the Minister called by Mr. Tardieu is Mr. Désiré Ferry, who is not a member of the medical profession, and is actually waiting for a staff and credits. The second creation has more interest at the moment, because no one knows what it will become in the future. The party for public health has been organised just like any political party. Its head is Senator Justin Godart, who was under-secretary to the military sanitary service during the war, where he did praiseworthy work. The party proposes to have sections all over France, and to submit candidates for election. But that is a trick to enable it to post bills on the reserved hoardings during electoral campaigns, and so oblige the ordinary candidates to consider public health questions. The first assembly of the party gathered a goodly concourse of people, and I have been told that subscriptions are coming in.

The New Institute for Cancer Research.

Since 1921 Prof. Roussy has been head of the cancer centre for the Paris suburbs, which I have already described. That centre has grown so quickly that it can no longer be contained in its present buildings. Two years ago Prof. Roussy negotiated an agreement between the State, the Paris administration, and the faculty for the foundation of a modern institute. The laboratory department of this institute was inaugurated with a great ceremony by the President of the Republic recently. It is composed of six groups of special laboratories, plus a post-mortem service. At the same time the President laid the first stone of the clinical section that is still working in the old pavilions. The laboratories have been in occupation for two months and are considered to be the best fitted in Europe for the present.

The Leeuwenhoek-Vereeniging.

Invited for the inauguration of the institute, the members of the Leeuwenhoek-Vereeniging held their third scientific meeting. This association for the study of malignant tumours was created in 1922 at Amsterdam, under the presidency of Prof. Rotgans, and the second meeting was held two years ago in London. The British members included Dr. J. A. Murray, Dr. H. J. B. Fry, Dr. E. L. Kennaway,

Dr. O. Guéniot, who is 98 years of age, has received from his fellow members of the Academy of Paris a medal to commemorate his fiftieth year of membership.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Child Welfare Legislation.

SINCE 1922 Federal aid has been available in the States under provisions of the Sheppard-Towner Act. In many of the poorer States it has proved almost indispensable to programmes of health education with especial regard to maternity and infant welfare. The Sheppard-Towner Act provided aid on the basis of \$5000 annually to each State and an additional \$5000 if matched by State funds. This was for five years only, but in 1927 the provisions of the Act were extended for an additional two years. The Act terminated June 30th, 1929. On April 18th, 1929, a Bill was introduced into Congress by Senator Jones and Representative Cooper which was in most respects identical with the Sheppard-Towner Act, except that no outright grant was offered to the States. It provided a million dollar appropriation to be administered by the Children's Bureau, which had administered the previous Act. This Jones-Cooper Bill was supported by all the child welfare organisations. These bodies, as well as some women's organisations, including the important League of Women Voters, had been favourably impressed with the working of the Act. It was approved by the American Medical Association, but with perhaps less confidence than was the original Sheppard-Towner Act, for medical societies in the poorer States are by no means solidly in agreement with the central administration. Yet the Jones-Cooper Bill was never voted. Representative Cooper has now introduced a substitute Bill which is unlikely to satisfy anyone. The appropriation is greatly reduced and the administration handed over to the Public Health Service. It has been questioned whether, under the provisions of this Bill, any of the money will be spent directly on maternity and infancy work. President Hoover is known to take great

personal interest in child welfare work, but it is clear that he cannot control the actions of Congress unless he has behind him a solid and vocal body of public opinion. However, the women's organisations are efficient and we may expect to hear from them in the near future.

Health in Prisons.

A series of prison mutinies has given impetus to the movement for psychiatric examination of convicted offenders. At a recent hearing of the New York State Crime Commission this policy was repeatedly emphasised. A suggestion for the establishment of a special court for boys between the ages of 16 and 18 was approved by a number of the commission. The need for relieving idleness among prisoners was also discussed. The situation in New York is certainly not worse than in other parts of the country if we are to believe the findings of a nation-wide survey of Federal and State penal institutions. More than 100 institutions are reviewed in the report of this survey, the health and medical aspects being presented by Dr. Frank L. Rector, the executive secretary of the Chicago Medical Society. "With few exceptions," he says, "the prison hospitals are greatly understaffed." Seldom is the physician also the administrative head of all health and hospital activities. The equipment in many prison hospitals leaves much to be desired. "Health education is badly neglected." It is recommended that actively tuberculous prisoners be not paroled unless adequate care by relatives is assured, but be transferred to a suitable institution for treatment. Recommendations are also made for the segregation of drug addicts and of the insane, as well as for the improvement of prison diet and of recreation facilities.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Death of Sir John Fagan.

THE recent death of Sir John Fagan, at Portarlington, removes from Irish medical circles a well-known public man. He obtained his medical qualifications from the Irish Royal Colleges no less than 65 years ago, and proceeding to the Fellowship of the Royal College of Surgeons in Ireland in 1874, must have been among the oldest, if not actually the senior, Fellow at the time of his death. He was for many years surgeon to the Royal Victoria Hospital, Belfast, but retired from practice in 1897 on his appointment as Inspector of Reformatories and Industrial Schools. Some years later he was appointed to the Prisons Board, and on the cessation of this office he went to live at Portarlington, where he died.

Royal Victoria Hospital, Belfast.

Captain H. G. H. Mulholland, Speaker of the House of Commons of Northern Ireland, presided at the 137th annual meeting of the Royal Victoria Hospital, held in the King Edward VII. Memorial Hall of the institution on March 28th. The annual report showed that during 1929, 6237 patients were treated in the wards, and extern patients numbered 55,090. The cost of running the hospital for the 12 months came to £81,643, against which the revenue was £59,812. The deficit is small, while it is of deep significance that important developments are taking place. The building of a new Maternity Hospital has actually begun, although £50,000 of the £130,000 required is still lacking. A scheme for a pay patients' department for people of moderate means—an urgently needed reform—is being held up pending the erection of a new nurses' home, but there is every hope that both will materialise. A fine new children's hospital is being erected close to the Royal Victoria, and the proposed housing of the Pathological and Bacteriological Department of the Queen's University in a new institute in the same grounds shows that the great scheme of having the whole medical school in the closest proximity to the clinical

hospitals is no longer a dream but is taking concrete shape.

Queen's University of Belfast.

At the spring graduation ceremony on March 28th the following degrees in the Faculty of Medicine were conferred:—

Doctor of Medicine—Samuel Hayes and Jane A. D. Maclean.
Bachelor of Medicine, Bachelor of Surgery, and Bachelor of Obstetrics—James H. Colhoun, Margaret M. Conway, Charles E. Emerson, George R. Garvin, Stanley B. Hughes, Robert F. Huston, William M. Bridge, Henry J. McShane, Gordon F. Magurran, Nora Mayblin, Phyllis E. Minford, Hector F. Northey, Thomas H. W. Ritchie, Cecil V. Stevenson, James B. Young, and Mary C. Young.

Diploma in Public Health—Letitia M. Allen, Eric Blackstock, William F. Lytle, Anna H. Park, and Thomas Purce.

Robert Harper Sproule, M.D., M.Ch.

Dr. R. H. Sproule, whose death took place at Killyleagh, County Down, on March 26th, was born in 1855 in County Tyrone, and took his university courses in Arts and Medicine in the Queen's College, Belfast, and graduated M.D., M.Ch., in 1881. He was appointed dispensary doctor for Killyleagh in 1888, and held that post until four years ago. Known and respected throughout a large part of Down his resignation from dispensary duties furnished his numerous friends with an opportunity of paying him a well-deserved presentation. Dr. Sproule had a remarkable memory. He could tell the birthday of every boy and girl born in his district during his period as medical officer. He was a noted "sermon taster" and woe to the clergyman who preached an old sermon in Second Killyleagh Presbyterian Church, as Dr. Sproule could repeat word for word any sermon heard for years back and could give the date of its delivery. He was a lover of all kinds of sport, especially cricket; ran the local football club, and presented all the necessary equipment to the boys. His memory will linger for a long time by the lovely shores of Strangford Lough, where his long life was spent in the unselfish service of others.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED.

MARCH 22ND, 1930.

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 361 (last week 433); scarlet fever, 2440; diphtheria, 1620; enteric fever, 55; pneumonia, 1462; puerperal fever, 47; puerperal pyrexia, 115; cerebro-spinal fever, 16; acute poliomyelitis, 3; encephalitis lethargica, 10; dysentery, 2; ophthalmia neonatorum, 115. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on March 25th–26th was as follows: Small-pox, 615 under treatment, 23 under observation (last week 587 and 26 respectively); scarlet fever, 2137; diphtheria, 2738; enteric fever, 18; measles, 1078; whooping-cough, 78; puerperal fever, 22 (plus 12 babies); encephalitis lethargica, 123; poliomyelitis, 1; "other diseases," 30. At St. Margaret's Hospital there were 12 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns including London there was no death from small-pox, 5 (1) from enteric fever, 119 (67) from measles, 16 (5) from scarlet fever, 35 (6) from whooping-cough, 40 (13) from diphtheria, 56 (16) from diarrhoea and enteritis under two years, and 67 (10) from influenza. The figures in parentheses are those for London itself.

The deaths from enteric fever outside London were reported from Reading, Birmingham, Bolton and York, each 1. The fatal cases of measles were concentrated at Manchester, 11; Sheffield, 8; West Ham, 5. (Glasgow also reported 15 deaths.) Whooping-cough claimed 8 victims at Birmingham; diphtheria 5 at Liverpool. Diarrhoea accounted for 6 deaths at Manchester and 4 at Liverpool. The highest figures for deaths attributed to influenza were Birmingham, 4; Stoke-on-Trent, 3. The monthly statement of deaths from small-pox in England and Wales for February contains one death assigned to Meltham U.D. (Yorks, W.R.).

The number of stillbirths notified during the week was 319 (corresponding to a rate of 48 per 1000 births), including 63 in London.

Correspondence.

"Audi alteram partem."

ATHLETICS IN SCHOOLS.

To the Editor of THE LANCET.

SIR,—I have read Dr. Lempriere's address and the discussion which followed its delivery in THE LANCET of March 29th with considerable interest, and must say that my experience has led me to agree with many of his conclusions. Unfortunately, I did not have the privilege of being present at the discussion at the Hunterian Society, but there are some points which, to my mind, cannot be too strongly stressed. The competitive spirit of athletics tends to be given too prominent a position in schools at the present day, and it is this concentration on the competitive factor, and the "cock-house" spirit, that forms the potential danger. Do we not all know how the Cup-tie keenness ruins hospital football and reduces the standard of play?

The recent realisation of the advantages of athletics as a means of sublimating that inherent dynamic energy that lies dormant in each and everyone of us has given sport an undue prominence in the public eye. School authorities have seen that by directing this energy along athletic channels they can obtain for it an outlet that prevents it from being manifested as mischief or immorality. Compulsory sublimation, however, is unsound, and for that reason I am definitely against compulsory games.

Dr. Simey strikes the correct note when he says that "spontaneity in recreation is essential," and in considering school games I would focus the attention, not on the word "athletics," meaning "contest," but on the word "recreation," meaning a refreshing or restoring of energy, and ask sports masters and others in authority to look upon the outdoor activities as an opportunity for the recreation of energy rather than as an expenditure to the limit of exhaustion. If the boys are thereby taught the right use of leisure it will be of lasting benefit to them all their lives, and we shall not have the tired and harassed business man dashing off at the week-end to take part in a strenuous golf competition which only leaves him still more tired and harassed at the end. The long road run, the cross country and competitive steeplechase are forms of recreation to be deprecated. Much greater benefit is derived from a medium course of one to three miles covered by a series of alternating hundred yards run and hundred yards walk, with an occasional fifty yards sprint. The efforts in such cases are short and sharp, monotony is avoided, and periods of comparative rest are provided.

Rowing is another sport that requires careful consideration. It is particularly fascinating, but unfortunately certain muscles are undoubtedly overworked at the expense of others, while the return flow of blood from the lower half of the body is not adequately provided for. Provided the individual is of good physique and sound constitution he will derive benefit from rowing, but otherwise he may do himself more harm than good. Certainly the middle-aged man, formerly a rowing man, is a distinct medical problem at the present day, though it is difficult to say how much of his disability is due to the rowing itself or to the faulty methods of training that were in vogue in the last century.

Rugby football, in that it requires a considerable "amount of contortional ability," would seem to stand fairly high in Captain Martin Flack's classification, but I think that it should not be widely indulged in by boys of preparatory school age. Its increasing popularity with the public of recent years has led to an outcry for speeding up the game and making it more spectacular, but the Rugby Union very wisely are averse to this, and base their legislation by visualising the normal schoolboy as the standard by which the game is ruled. To speed up the game beyond the capabilities and

endurance of lads of 16 would be detrimental both to the game and the youth of the nation. I would encourage junior boys below public school age to engage in running, gymnastics, and Association football as their winter pastimes, while boxing and Rugby football can be developed later.

Sport certainly plays a big part in character building and in the development of the adolescent, but in certain quarters it is apt to bulk too largely in the curriculum. We must guard against making a fetish of games and neglecting other forms of recreation. Fatalities are few, and my limited experience coincides with that of Dr. Lempriere in bearing out the truth of Sir Clifford Allbutt's dictum. It is almost impossible for a healthy trained athlete to dilate his heart, and the young adolescent has a wide margin of elasticity. When trouble does occur it is usually the result of faulty training, or due to excessive exercise following some infectious disease, such as tonsillitis, influenza, subacute rheumatism, &c., the significance of which has not been recognised. Consequently, adequate supervision is essential. The fallacies do not seem to lie in the games themselves, but in the administration when it is carried out by enthusiastic but inexperienced prefects or young over-zealous housemasters, while the frequent fostering of the competitive spirit, and the glorification of the individual, are bound to have detrimental effects.

I am, Sir, yours faithfully,

R. COVE-SMITH.

Cambridge-terrace, Hyde Park, W., March 31st, 1930.

To the Editor of THE LANCET.

SIR,—Neither in the very interesting paper on Athletics in Schools, read by my friend Dr. Lempriere before the Hunterian Society, nor in the subsequent discussion, does there seem to have been any adequate consideration of diet in relation to athletic heart strain. Dr. Lempriere very properly emphasised the fact insisted upon by Bainbridge in his Physiology of Muscular Exercise, that "not only is the heart normally equal to the demands placed upon it, but in a perfectly healthy man even the most intense exertion of which he is capable has no harmful effect upon the heart."

Of the causes which render a heart unhealthy to the point where it strains on relatively slight exertion, Dr. Lempriere finds trifling attacks of influenza to be the most redoubtable, because they are liable to go unnoticed—a matter in which every one will agree. It is probable that the heart, like other organs, has its favourite poisons so to speak, and that among the more acute kind those of influenzal and kindred air-passage infections are the most frequent, except, of course, the truly rheumatic. But there are other toxins of a more chronic kind, which render the heart liable to strain under seemingly slight provocation, and they are the toxins which come from within. These are even more redoubtable than the toxins of the influenzal type, not only because no one seems to remember them, but because boys vary enormously in their susceptibility thereto. And these endogenous toxins can only come from faulty dietetics—a moment's consideration compels this conclusion.

I realise that in large communities it is very difficult indeed to cater for the physiological non-conformist, but I think that although recent advances in dietetics have vastly improved matters in most schools, there still remains room for much reasonable reform. Why, for instance, is a lusty lad—whose face is covered with acne, given large and repeated slabs of butcher's meat at school, when it has been proved that the absent slabs in the holidays means the disappearance of the acne? And if this can happen it is more than likely that poisons similarly generated can functionally tarnish the heart. I am personally persuaded that a good many albuminurics come into a closely neighbouring category.

I am, Sir, yours faithfully,

LEONARD WILLIAMS.

St. James's-place, S.W., March 28th, 1930.

thought, however, it would be a great mistake to limit the assessors to a panel of names recommended by the President of the British Medical Association. He thought it would be a great mistake to bring that Association into the matter at all. A large number of medical men were members of the Association; on the other hand, they knew that it represented the most reactionary and commercial section of the profession. He felt very strongly that discretion should either be left to the Lord Chancellor, or if they wanted to bring in a medical body, they should bring in the scientific and not the commercial section, for instance, the President of the Royal College of Physicians.

Miss LAWRENCE (Parliamentary Secretary to the Ministry of Health) said it was impossible to accept the proposal for the nomination of a medical assessor. The whole spirit of the High Court was contrary to the idea of introducing expert assessors into the question whether a person had acted with reasonable care and good faith. She wanted to say to those who thought that they were giving too much protection to doctors in this matter that there was a real danger of frivolous and even insane complaints. Before the machinery of prosecution was set in motion there ought to be some responsible person to see if there was anything in the complaint worth sending to a jury. The Government were accepting in substance the first amendment in the name of Colonel Fremantle. They could not accept his words for a good many reasons. She suggested that Colonel Fremantle, having seen the Government amendment, which would come up on the Report stage, should now withdraw his own amendment.

Lieut.-Colonel Fremantle said he would withdraw his amendment on the understanding that it should be put on the paper for the report stage alongside the amendment of the Minister for the purposes of comparison.

The amendment was withdrawn.

Lieut.-Colonel FREMANTLE moved at the end of Sub-section (1) to insert the words:—

"For the purpose of determining any question under the preceding Subsection the Court may, at its discretion, sit with one or more assessors nominated by the Lord Chancellor from a panel of names recommended by the President of the British Medical Association."

Dr. VERNON DAVIES moved as an amendment to the proposed amendment to leave out the words "from a panel of names recommended by the President of the British Medical Association."

Mr. GREENWOOD said if he were forced to accept an amendment on these lines, he would favour the amendment to the amendment, but that did not in his view destroy the case against the amendment.

The amendment to the amendment was agreed to.

The motion that "the proposed words as amended be there inserted" was negatived by 18 votes to 9.

Clause 16 as amended was added to the Bill. Clause 17 (Amendment of Section 11 of the principal Act) was also added to the Bill.

The Committee adjourned.

The Mental Treatment Bill was further considered by Standing Committee A of the House of Commons on Tuesday, April 1st. Mr. CECIL WILSON was in the chair.

Various Amendments.

On Clause 18 (Provision as to rate-aided patients) and Clause 19 (Amendment as to persons of unsound mind liable to be removed to workhouses),

Mr. GREENWOOD, Minister of Health, moved amendments providing that both clauses should come into operation immediately on the passing of the Act. He said that this was necessary for the purpose of synchronizing the operation of these clauses as far as possible with the Local Government Act which came into operation that day.

The amendments were agreed to.

On Clause 20 (Substitution of name "mental hospital" for the name "asylum," and expression "rate-aided" for expression "pauper,"

Mr. GREENWOOD moved the following amendment:—

Any provision in any local Act for the reception of voluntary boarders into any institution shall have effect as if for references therein to "voluntary boarders," there were substituted references to "voluntary patients," and any reference in this Act to persons received as voluntary patients, or as patients, under any local Act shall be construed as including a reference to persons received before the commencement of this Act as voluntary boarders under any such Act.

The amendment was agreed to.

Dr. MORRIS-JONES moved amendments to provide that after the passing of the Act the word "lunatic" as well as "pauper" should cease to be used and that the phrases "mental patient" or "person of unsound mind" should be substituted.

Mr. GREENWOOD said that there were certain administrative difficulties in the way of entirely getting rid of the term "lunatic" in an Act of Parliament, but if the Committee

felt strongly on the matter he was willing to move an alternative amendment providing that the word "lunatic" should no longer be used in any Act or Order except in relation to criminal lunatics or persons detained as lunatics outside England.

Dr. MORRIS-JONES said that if the Minister assured the Committee that the term "lunatic" would only be used when it was absolutely necessary for administrative reasons he would withdraw his amendment.

Mr. GREENWOOD explained that the phrase "outside England" meant Scotland and Northern Ireland.

Dr. MORRIS-JONES's amendment was withdrawn. Mr. Greenwood then moved his alternative amendment, and this was agreed to.

Clause 20 was added to the Bill.

On Clause 21 (Interpretation and adoption),

Mr. GREENWOOD moved an amendment providing a revised definition of the phrase "person in charge." This was declared to mean

"in relation to a person received or about to be received under this or any local Act as a voluntary or temporary patient (not being a person received, or about to be received, as a single patient) the medical superintendent or other person in charge of the institution, hospital, home, or place into which he was, or was about to be, so received, and in relation to a person so received, or about to be so received, as a single patient, the phrase meant the person into whose charge he was, or was about to be, so received."

The amendment was agreed to.

Mr. GREENWOOD moved an amendment deleting the sub-section extending "local authority" to include the Lancashire Mental Hospitals Board, the West Riding Mental Hospitals Board, and the Staffordshire Mental Hospitals Board. He gave an undertaking that before any rules affecting these bodies were made by the Board of Control he would take into consultation not only the hospitals boards, but the county boroughs concerned.

The amendment was agreed to and Clause 21 was added to the Bill.

Clause 22 (short title, &c.) provides that the Act shall not apply to Scotland or Northern Ireland.

Miss LAWRENCE (Parliamentary Secretary to the Ministry of Health) said that it was necessary to exclude these countries, which had different legislation.

The clause was added to the Bill.

Financial Obligations.

Some discussion took place on the financial obligations which were likely to be thrown upon local authorities as a result of this Bill, and Mr. Greenwood was pressed to give assurances that the Exchequer would give assistance to local authorities to meet those new obligations.

Mr. GREENWOOD said that the local authorities would not be precluded from coming at the end of the first block-grant period for a revision of their grant in respect of any additional expenditure thrown upon them.

Lieut.-Colonel FREMANTLE moved a new clause providing for the auditing of the accounts of licensed houses.

Mr. GREENWOOD, while accepting the principle of the new clause, said that he would prefer different wording. He suggested that the following new clause ought to meet the hon. Member's purpose:—

1. The licensee of every licensed house shall cause such accounts to be kept as the Board of Control may prescribe. Those accounts shall be audited once a year in such manner and by such person as the Board direct.

2. A copy of the accounts and of the report of the auditor thereon shall be sent by the licensee to the Board of Control who, if they think fit, may publish them in whole or in part.

3. The licensee shall pay to the auditor such fee in respect of the audit as the Board of Control shall direct.

He said that it was intended to use the services of the official auditors for this purpose.

Lieut.-Col. FREMANTLE accepted the wording of the Minister's clause in substitution for his own and Mr. Greenwood's clause was then agreed to.

An amendment was agreed to in the First Schedule providing that a medical practitioner in filling up forms of recommendation for temporary treatment should distinguish between facts relating to the patient based on his own observation and facts communicated to him by others.

The Committee adjourned.

CARDIFF CORPORATION BILL.

On March 25th the Local Legislation Committee (Section B) of the House of Commons considered the Cardiff Corporation Bill. Mr. CAPE was in the chair.

Medical Secrecy and Cases of Cancer.

One of the Clauses of the Bill proposed to give the Corporation power to pay any medical practitioner a fee of 2s. 6d. for the notification of a case of cancer in his private practice, or 1s. for a case met with in public practice.

Dr. PICKEN, medical officer of health for the city of Cardiff, giving evidence in support of the clause, said that there had been in operation for some time in Cardiff a system to enable the authorities to ascertain the housing conditions and mode of life of persons suffering from cancer. That system was inaugurated on the assumption that it was authorised by an Act of 1925. It was now desired to put the matter beyond doubt as to legal authority.

In reply to Captain R. HENDERSON (a member of the Committee), Dr. PICKEN said the main object was to get in touch with cancer patients. One advantage would be that it would help in getting such patients into hospital in cases where early treatment was essential.

Captain HENDERSON: Will not this proposal involve a breach of confidence between a patient and his medical adviser? It seems to be a fee or bribe to a medical man to divulge the illness from which a patient is suffering.

Mr. J. H. PALIN (another member of the Committee): Surely not for half-a-crown.

Dr. PICKEN said that the clause laid no duty on a medical practitioner.

Captain HENDERSON: Have you submitted the clause to the medical authorities?

Dr. PICKEN said that the clause was the outcome of discussion by a committee consisting of experts and medical practitioners who approved the proposal.

After further discussion the Committee decided that the clause must be struck out of the Bill.

SLUM CLEARANCE BILL.

On Thursday, March 27th, Mr. GREENWOOD introduced the Housing (No. 2) Bill, a measure to make further and better provision with respect to the clearance or improvement of unhealthy areas, the repair or demolition of insanitary houses and the housing of persons of the working classes; to amend the Housing Act, 1925, the Housing, &c., Act, 1923, the Housing (Financial Provisions) Act, 1924, and the other enactments relating to housing subsidies; and for purposes connected with the matters aforesaid.

The Bill was read a first time.

PHARMACISTS IN POOR-LAW HOSPITALS.

On Monday, March 31st, on the motion for the adjournment.

Captain GUNSTON raised the question of the position of pharmacists in poor-law hospitals, as it was affected by the Draft Poor Law Order which had been published by the Ministry of Health called the Public Assistance Order, 1930. He said that the pharmacists were very much concerned about this Order, because they felt that the status of the members of their profession employed in poor-law hospitals would be very seriously jeopardised. In the voluntary hospitals pharmacists were independent officers in charge of their own department. In the Navy pharmacists were of equal rank with schoolmasters and medical officers. He urged that if this was the position in these two cases, the status ought to be given by local authorities. It was not claimed that the Minister should compel the authorities to give the same status to pharmacists, but only that authorities should be allowed to decide whether they would do so or not. They did not ask for more control, but simply that these matters should be left in the hands of the local authorities.

Miss LAWRENCE said that if that were all that was asked, she could answer in one word, Yes. This was not a new Order. It was an old Order, revised and reprinted, and nothing more. There was no modification of substance. The only modification was the verbal one necessitated in the change in the names of the new authorities. If local authorities desired that a pharmacist should be a chief officer, they could recommend the matter to the Ministry, and discuss it with him, and even appoint him as chief officer before the Minister examined the question. The assurance was given to the local authorities by the previous Government that any amendment or modification with regard to superior officers should not be made until after consultation with the authorities. If any amendment was desired it could be made subject to consultation with the local authorities. The Ministry had changed nothing. They had not made it impossible for these people to be appointed. In these matters, as in every other, they had left the position as it was, for consultation with the new authorities.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 26TH.

Medical Education for the Navy.

In reply to Dr. VERNON DAVIES,

Mr. ALEXANDER, First Lord of the Admiralty, stated that professional courses were held at the Royal Naval Medical School. The amounts included in the estimates for

naval courses at Greenwich, exclusive of the Staff and War Colleges and the Medical School, for 1928, 1929 and 1930, were £78,500; £78,130; and £77,000 respectively. Vaccines used in the Navy were produced at the Medical School, Greenwich, except the anti-small-pox lymph.

Medical Officers in the Army.

Dr. VERNON DAVIES asked the Secretary of State for War if he would give for each of the last ten years for which statistics were available the total number of medical officers in the Army, the number who joined, and the number who left the service in each year.—Mr. T. SLIAW gave the following table showing the total number of Regular Officers, Royal Army Medical Corps, serving in the Army by years from 1923 inclusive, together with the number who joined and the number who left the service each year.

Year.	Strength on Jan. 1st.	Joined.	Retired, resigned or died.
1923	989	11	89
1924	911	12	53
1925	870	9	47
1926	832	13	52
1927	793	20	38
1928	780	28	34
1929	754	28	32

THURSDAY, MARCH 27TH.

Report on Poisons and Pharmacy Acts.

Sir KINGSLEY WOOD asked the Home Secretary whether he could make a statement as to the Government's intentions concerning the Report of the departmental committee on the Poisons and Pharmacy Acts.—Mr. CLYNES replied: The Government recognise the importance of this report and will take it into consideration as soon as possible, but there is no prospect of their introducing the comprehensive legislation which would be required to give effect to the committee's recommendations this session.

Criminal Offences against Children.

Captain PETER MACDONALD asked the Home Secretary whether it was his intention to introduce a measure amending the Criminal Law in relation to children and young persons; and, if so, whether the Bill would be brought in during the present session of Parliament.—Mr. CLYNES replied: It is the intention of the Government, as I have stated in reply to previous questions, to introduce a Bill to amend the Children Act, 1908; but I regret that it is impossible in view of the pressure of Parliamentary business to take the Bill this session.

Street Offences.

Mr. GRAHAM WHITE asked the Home Secretary if it was the present intention of the Government to introduce legislation to give effect to the recommendations of the Street Offences Committee.—Mr. CLYNES replied: I regret I do not see my way at present to introduce legislation upon this subject.

Quality of Margarine Materials.

Mr. CHARLES WILLIAMS asked the Minister of Health if imports of oleo oil and oleo stearine used in margarine must be accompanied by a certificate that the fat was derived from animals free from disease.—Mr. GREENWOOD replied: It is not the practice at English ports to require such a certificate.

Tuberculin-tested Animals and Exhibition Order.

Mr. RAMSBOTHAM asked the Minister of Health whether he had received any protests from agricultural societies regarding the order he recently issued, prohibiting the exhibition at agricultural shows of animals from tuberculin-tested herds; and, if so, whether, in view of the hardship caused by the imposition of this order, he would reconsider the advisability of introducing it.—Mr. GREENWOOD replied: Yes, Sir. I have been informed that some of the bodies responsible for the organisation of agricultural shows are now prepared to arrange for the segregation of animals belonging to licensed tuberculin-tested herds, and I have promised to see their representatives with a view to considering the withdrawal of the prohibition in the case of shows where effective provision is made for this purpose.

Deposit Contributors and National Insurance.

Mr. THOMAS LEWIS asked the Minister of Health if he would state for the year ending December, 1929, the number of applications received for admission to the insurance section of the deposit contributors' fund in accordance with Section 11 of the National Health Insurance Act, 1928, and the number of such applications which had been accepted and rejected, respectively, with details of the causes

death-rates are due to the habits of the dementia præcox patients and not to any close relationship of the physical to the mental disorder." From my own very slight experience, I am inclined to the view expressed by Dr. Pollock—viz., that the tuberculosis is a consequence of, and not a cause of the insanity.

Yet the average sufferer from tuberculosis is far from normal. This, I think, must be ascribed to many factors, of which the toxæmia may be one, in that it entails a general lowering of vitality, thus decreasing the resistance which the patient can offer to any disturbing influence. He is, in consequence, much less able to solve his problems and is, therefore, much more liable to a breakdown should any difficulty arise in his life. And with such difficulties the life of the victim of tuberculosis is fraught, and as a result we get many abnormal symptoms, which are not produced by the disease directly, but which are caused by the difficulty of living. In my opinion such mental symptoms may be expected to occur in any disease or illness which is painless and long, and which involves the individual in difficult problems.

As has already been indicated the disease has usually a long history before diagnosis, and hundreds, nay thousands, of apparently healthy people are in reality already far gone in tuberculosis. They are not, perhaps, the most advanced of them, feeling very fit. They have coughs and colds, but they will "be all right in a day or two," and so they carry on, sometimes better, and sometimes worse, putting off the evil day when they must meet the doctor. It is a strange fact that a medical examination should be regarded with such terror, unless one is really ill. Who, even the fittest of us, does not know the feeling of relief when our medical examination, say for an assurance policy, is over? And so the individual carries on, a little more weary, perhaps, a little more irritable with his people at home, and his friends possibly thinking him rather a slacker; or, if cast in another mould, he carries on in spite of his feeling of lassitude, priding himself on the fact that he so seldom misses a day's work. Then one day he is examined, either going of his own free will, or being forced to call on the doctor owing to a hæmorrhage. Of these two cases the latter is the easier one to treat. The patient and his people have had a rude shock. They are all thoroughly frightened. Something must be done and that quickly; so, though the effect of the hæmorrhage may be physically slight, treatment is undertaken at once, and there is hope. The one who has not had such an experience goes on hoping and perhaps persuading himself that the diagnosis is not correct. He is in consequence much less likely to follow out the treatment which is necessary.

Reaction when Diagnosis is Made.

The reaction of patients when the diagnosis is made is very variable. The patient may take it calmly, obviously realising the verdict and all its implications; or he may break down completely—a big, strong-looking fellow bursting into a flood of tears; or the doctor's statement may be received with indifference, the patient acting as though the diagnosis were of no account or at least as though he believed the doctor had made a mistake. These reactions are, I consider, valuable to the doctor, and should be carefully noted. They show the attitude the patient is adopting towards his illness, and this attitude is important for his future welfare. The one who faces the facts calmly with full realisation is already beginning the struggle bravely, a great actor in his favour; the one who breaks down may be comforted and after the first shock may be put up a brave fight; but the third has already decided to throw in his hand. He dare not face the situation, and will do all manner of foolish things to prove that the diagnosis is incorrect, often with disastrous results. Such an one requires careful attention. It is not sufficient to send him away from the consulting-room muttering under one's breath that one can do nothing for fools. One can do nothing with fools, but one can endeavour to prevent them from being fools. Half an hour later by the doctor at such a time will save many a weary hour later.

It is hard for us who have had to do with the diagnosis of tuberculosis to see a man, often with a wife and family and a comfortable home, with a business which is secure and which is steadily growing, and with a future which seems so assured—a man to whom the world appears a lovely place with its bright spots far outnumbering the few clouds which serve but as a contrast to what is so pleasant—such an one is told he has tuberculosis. Gone is his future; no more can he compete in his business; the holiday he had so joyously planned must not be; his children's education must now be modified; the house must be sold; his wife must go out and work. Not only is he himself no longer a breadwinner, he is instead bound to be a heavy and constant expense through the long and wearisome illness, which can end in but one way. It is a brave man who can face such a situation unafraid. But the state is even worse than this, for the man is no longer able

to mix freely with his fellow men. His friends are chary of asking him to their houses for fear lest he should infect them or their children; if he coughs all eyes turn in his direction. He is now an outcast. This is a terrible experience, and the patient plumbs the depths. Is it surprising that he gives way to despair?

Result of Individual Sentiment.

The best patients are those who will face the facts; but most, even of them, go through a period of great depression, and are very liable to break down. The most satisfactory patients are often, in my opinion, the married. This may seem strange, for they have others dependent on them and their worries accordingly, one would think, must be greater than the worries of those who are not "hampered" with a wife and family. This is quite true in one sense; but there is another factor, which is that the married man often has a strong sentiment organised round his family, and for their sakes he "will" get well. The unmarried man, all too often, has as his chief sentiment a peculiarly self-centred one. He is ambitious; he would have been such a good boxer or footballer, or something of that kind. He now has nothing to live for. What is the use? He can no longer go about and have a good time again, and—down he goes. Here, I think, we touch on a very vital problem in the study of tuberculosis. It is the organisation of the individual's sentiments which is of prime importance—a man with his principal sentiments organised round some ideal, which is not ego-centric, is liable to better organisation caused by the disease, than is a man whose life has no necessary thrill, whose chief sentiment is ambition, or other self-centred sentiment, loses morale at once. He tends to go off into day-dreams of what might have been, or of what may still be if he is only cured quickly. He rails against his misfortune. Why is it that he is so much more hardly dealt with than are others? He is for ever looking at his thermometer and watching his symptoms; the least little thing puts him back, and he becomes a valetudinarian, and rapidly acquires the sanatorium habit, going round from one sanatorium to the next, ever more depressed, and going steadily down with little respite at every new sanatorium. Such patients are very difficult to treat. They cannot reorganise their lives.

At the same time, the general lowering of vitality, the result largely of the toxæmia, exacerbates any weakness already present. The many conflicts, which every individual has to face, and with which the majority of normally healthy individuals can cope satisfactorily, are beyond their strength, and the patient worries and worries, and loses his sleep. Rest is one of the main planks in the treatment, but lying in bed doing nothing but worry is not resting. Rest, lying down doing nothing, is the one thing such a patient cannot do. He cannot rest. He is filled with a feverish restlessness which is so often apparent and which is so very harmful. He becomes peevish and irritable, and a great trial to his nurse. Wingfield's remarks over and over again on the importance of searching for these worries, which he says, "may seem trivial, but . . . are really all-important." This is true; but the secret of treatment is not in the prescription of pot. bromide. Such treatment is, in my opinion, fundamentally wrong, and would be perhaps as useful as giving a man bromide for a broken arm. Nor is the secret of treatment to be found in work, assuming the patient is physically fit to work, which so often is not the case, for it is not occupation which is wanted; the mind is already more than fully occupied with its worries. The value of work is not to be denied. Its value is enormous, when organised as it is at Papworth, for the simple reason that it is the solution of the majority of the worries, not because it gives the patient something to think about. The patient sees that he can still work and earn a decent living, though in a different manner perhaps than when he was well. But work is not sufficient in these cases. No! The difficulties and worries must first be gone into and straightened out if progress is to be made. There was one such at Papworth in October last. He came to Papworth after four years' treatment elsewhere, during almost the whole of which time he had been given bromides because he never slept on account of his worries. Three-quarters of an hour on two separate days solved his difficulties. He began immediately to sleep well, and has had no relapse since.

Neurosis and the Spcs Phthisica.

Sometimes patients may develop serious neuroses. Their treatment, psychologically, must follow the usual lines, but it is always to be considered whether the patient's state physically is such as to warrant proceeding further with such treatment.

We now come to that extraordinary state of hopelessness into which so many patients fall before the end; a pathetic state in which the patient, with scarcely strength to move

Vacancies.

 Cambridge, Addenbrooke's Hospital.—H.P. and H.S. Each at rate of £130.
 Connaught Hospital, Orford-road, E.—Sen. Res. H.S. At rate of £150. Also Jun. Res. H.S. At rate of £100.
 Derby, Derbyshire, Royal Infirmary.—H.P. £150.
 Doncaster Royal Infirmary.—Hon. Phys. and Path. Hon. Ear, Nose and Throat S. Also Two Hon. Anaesthetists.
 Downpatrick, Down Mental Hospital.—Jun. Asst. M.O. £300.
 Dundee Royal Infirmary.—Two Asst. Visiting M.O.'s.
 Durham County Council.—Asst. M.O. for Public Services. £300.
 Durham County Hospital.—Jun. H.S. £120.
 East Ham Memorial Hospital, Shrubbery-road, E.—H.P. and Cas. O. At rate of £150.
 Edinburgh Corporation.—M.O.H. £1500.
 Evelina Hosp. for Children, Southwark, S.E.—H.S. At rate of £150.
 Folestone Borough.—Asst. M.O.H. £600.
 Halifax Royal Infirmary.—First H.S. also Thrd H.S. At rate of £175 and £100 respectively.
 Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—H.S. At rate of £100.
 Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. £50 for six months. Jun. H.P. At rate of £100.
 Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. and H.P. At rate of £150 and £100 respectively.
 Hospital for Women, Soho-square, W.—Res. M.O. At rate of £100.
 Hove, Lady Chichester Hospital.—Jun. H.P. £50.
 Huddersfield County Borough.—Asst. M.O.H. £300.
 Inverness, Northern Infirmary.—H.P. £100.
 Indian Medical Service.—Commissions.
 Kenya Colony.—Medical Officer.
 King Edward Memorial Hospital, Ealing, W.—Sen. and Jun. H.S.'s. At rate of £150 and £100 respectively.
 Lincoln County Hospital.—Jun. H.S. At rate of £150.
 Liverpool, St. Paul's Eye Hospital.—H.S. At rate of £120.
 London Homoeopathic Hospital, Great Ormond-street, and Queen-square, Bloomsbury, W.C.—Res. M.O. £100.
 London Jewish Hospital, Stepney Green, E.—Med. Reg. and Out-patient Asst. At rate of £150.
 Manchester Ear Hospital, Grosvenor-square, Ill Saints.—H.S. At rate of £150.
 Medical Inspectors of Factories.—£600.
 Metropolitan Hospital, Kingsland-road, E.—Sen. H.P., Sen. H.S., Jun. H.P., Jun. H.S. Also Two Cas. O.'s. All at rate of £100.
 Montrose Royal Asylum.—Asst. M.O. £225.
 Newcastle-upon-Tyne, Hospital for Sick Children.—Jun. H.S. Also Res. Sen. H.S. At rate of £100 and £95 respectively.
 Nottingham General Hospital.—Second Cas. O. At rate of £150.
 Preston and County of Lancaster Royal Infirmary.—Pathologist. £1000.
 Princess Louise Kensington Hospital for Children, North Kensington.—H.P. At rate of £75.
 Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Res. Anaesthetist. At rate of £80.
 Queen's Hospital for Children, Hackney-road, E.—H.S. At rate of £100.
 Royal Eye Hospital, St. George's Circus, Southwark, S.E.—H.S. Also Asst. H.S. At rate of £150 and £100 respectively.
 Royal Free Hospital, Gray's Inn-road, W.C.—Cas. O. At rate of £150. Also Res. Anaesthetist.
 Royal Northern Hospital, Holloway-road, N.—Pathologist. £750. Also Asst. Pathologist. £500.
 Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.S. At rate of £100.
 St. Bartholomew's Hospital, E.C.—Chief Asst. to Dental Dept., also Dental H.S. At rate of £80.
 St. Helen's Hospital, Lancashire.—Res. M.O. £250.
 St. John's Hosp., Lewisham, S.E.—Res. Cas. O. At rate of £100.
 Salford Royal Hospital.—H.P. also Cas. H.S. Each at a rate of £125.
 Samaritan Free Hospital for Women, Marylebone-road, N.—H.S. At rate of £100.
 Southampton, Royal South Hants and Southampton Hospital.—Cas. O. At rate of £130-£160.
 Stafford County Mental Hospital.—2nd Asst. M.O. £600.
 Stockport Infirmary.—H.P. £175.
 Tiverton Hospital.—H.S. At rate of £100.
 Wakefield, Clayton Hospital.—Two H.S.'s. Each at rate of £150.
 Walsall General Hospital.—Cas. H.S. At rate of £150.
 Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. Res. H.S. Also Jun. H.S. At rate of £150 and £100 respectively.
 Winchester, Royal Hampshire County Hospital.—Hon. Anaesthetist.
 The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Soham (Cambridgeshire).

Notes, Comments, and Abstracts.

SOME PSYCHOLOGICAL OBSERVATIONS ON ADULT MALE TUBERCULOUS PATIENTS.

By H. BANISTER, M.Sc., PH.D. CAMB.,

LECTURER IN EXPERIMENTAL PSYCHOLOGY, UNIVERSITY OF CAMBRIDGE; AND HON. PSYCHOLOGIST, PAPWORTH VILLAGE SETTLEMENT.

For the understanding of the mental outlook of patients suffering from tuberculosis it is necessary that the salient facts of the disease itself should be known.

Underlying Pathology of the Disease.

Tuberculosis, which is essentially a disease of civilisation appears in two main forms. The forms are not mutually exclusive, but merge into each other. The first type is an acute generalised tuberculosis in which the lungs are affected as a part of the general infection. This is the most severe type, and is the form the disease generally takes when introduced into uncivilised lands. It is the form most prevalent in infancy, and is responsible for about one out of every three infantile deaths. If an infant which has been infected survives, the result is a certain amount of immunity; so that, between infancy and puberty, children are particularly free from tuberculosis. But at puberty there is a sudden increase in the death-rate. The disease is now of the second type, which consists most commonly of chronic pulmonary lesion, often without any tuberculosis anywhere else. The death-rate falls gradually as the sex life wanes. As a rule, proneness to the disease begins earlier and subsides earlier in women than in men. These facts may possibly be of significance.

One other point, and a most important one for us, is that, in general, the disease is painless. There is actual destruction of the tissue—e.g., of the lung—and a general toxæmia; but except in special cases—e.g., in pleurisy—there is no pain and little active discomfort. The patient feels disinclined to exert himself, and may complain of a general slowness. Otherwise there is little to indicate to him the seriousness of the malady with which he is attacked. From the nature of the disease it is obviously very difficult—at present it is impossible—to effect a "cure." The utmost that can be done is to arrest the progress of the disease; but the loss of tissue remains and the infection is always there and may at any time break out anew. As R. C. Wingfield¹ says, "No patient can be said to be cured till he is safely dead of some other disease." As an example of this I may give the case of a patient at Papworth. The disease was arrested, and he was working, was well, and was happy. He was also very keen on the stage, and was very anxious to see Mrs. Patrick Campbell in "Magda." Contrary to medical advice he went, was very thrilled by the play, and . . . died within the week.

Mental Consequences.

So much for the pathology of the disease. What of the mental consequences? These are many and widespread, though whether there is any definite insanity which is to be connected with tuberculosis is open to doubt. S. A. Knopf² considers that there is no definite pathological outlook which is connected with tuberculosis. D. G. M. Munro,³ on the other hand, considers that there is a phthisical insanity—an example of an exaggeration of ego-centricity—and that the symptoms may be regarded "as generally falling within two main groups: (a) mania of a mild delusional kind, and (b) melancholia." T. S. Clouston⁴ also points out that the death-rate from pulmonary tuberculosis in the Royal Edinburgh Asylum, during the decade 1879-88, was higher than that in the general population as 3:1, and suggests that the reason why so few cases of insanity occur in sanatoria is that the mental symptoms declare themselves first. The connexion between dementia præcox and tuberculosis is commented on by Dr. Pollock, of the Department of Mental Hygiene, New York, in a private letter to me as follows: "The question of the relation of dementia præcox to tuberculosis has been raised on account of the high rates of death of dementia præcox patients from tuberculosis. It seems probable, however, that such high

Hunterian Lecture

ON

PERFORATING WOUNDS OF THE EYEBALL.

Delivered before the Royal College of Surgeons of England on Feb. 5th, 1930.

By J. HERBERT FISHER, M.B., B.S. LOND.,

FELLOW AND MEMBER OF COUNCIL OF THE COLLEGE; CONSULTING OPHTHALMIC SURGEON TO ST. THOMAS'S HOSPITAL; CONSULTING SURGEON TO THE ROYAL LONDON OPHTHALMIC HOSPITAL.

We live in a restless and progressive age. So much that is new is evolved in so short a time that in all branches of medicine there is the risk lest in our endeavours to keep abreast with the times we succumb to the temptation to lighten the load by jettisoning the sound knowledge of the past. Anticipating that among my hearers might be found a proportion of women and men about to embark in the practice of ophthalmology, I have thought that some lessons drawn from my clinical experience might be of interest and of value.

CASE 1.—In November, 1900, a boy of 17 at one of our public schools was mixing carbon, sulphur, and chlorate of potash with a pestle in a mortar when a violent explosion occurred, and all the windows of the chemical laboratory were broken. I saw the patient some six hours later suffering much from shock, with great laceration of his hands, which became permanently crippled, while powder grains were abundant in the skin of his cheeks, nose, forehead, and eyelids. Foreign particles were embedded in the cornea and sclerotic of each eye, and in the right there was a punctured wound at the highest point of the limbus. The iris was lacerated but not prolapsed and the lens wounded and becoming opaque. A good anterior chamber was present, and the eyelids were ecchymosed and oedematous. It was not until three weeks later that his general condition allowed me to deal with the traumatic cataract. Two examinations with X rays had failed to show the presence of any intraocular foreign body, but on evacuating the soft cataract a small fragment of porcelain appeared through a rent in the posterior capsule of the lens, and I was able to pick it out with forceps through the corneal incision. A small quantity of vitreous was lost. The eye subsequently did very well, and with correction for its aphakia obtained full direct vision, and to my knowledge still had 6/6 nearly five years later.

CASE 2.—On the evening of Sept. 9th, 1903, in Scotland, the members of a shooting party, having had a wet day, amused themselves by throwing into the fire percussion caps which they cut from soaked cartridges. One of the explosions, more violent than the rest, resulted in the right eye of a young man being struck with some fragment, but whether of coal, stone, or copper could not be determined. The next day the ophthalmic surgeon whom he consulted in the nearest large town advised immediate removal of the eye. The patient, however, decided to come to London, and I saw him two days after the accident. His right eye presented a large irregular gaping wound in the sclerotic through which vitreous was protruding. The wound was situated to the nasal side and over the posterior part of the ciliary body. The aqueous chamber was deep, as the result of the loss of vitreous, and contained a little blood. Use of X rays was obviously undesirable until the wound became cold, and I sent the patient immediately into a nursing home to maintain absolute rest. The next day the anterior chamber was very deep, in consequence of more vitreous having exuded in spite of my attempt to draw the wound together and protect it with ocular conjunctiva under a general anesthetic. I banded both eyes and ordered that he be kept entirely recumbent and at rest on his back, but the patient was young and not very precise in observing my instructions. The scleral wound, however, healed slowly. On October 6th, 1903, an X ray examination was made by the late Sir Mackenzie Davidson, who reported that there was no foreign body present, either in the eyeball or the orbit. The eye was left slightly astigmatic but had 6/6 vision with a weak cylinder lens. By the end of the year he was again shooting and playing golf, and the eye kept permanently well.

These two cases indicate that detachment of retina need not by any means follow when healthy vitreous is lost, either anteriorly or through a wound of the sclerotic. In each instance the flying particle which inflicted the ocular wound—in the first case retained, in the second not retained within the eyeball—was no doubt sterilised by the heat engendered by the explosion. This fortunately is also the case where fragments of flying steel or other metal injure the eyes of workmen when chipping metal or grinding tools in engineering shops; the fragments often come off at a white heat from the impact of a steel hammer on a steel chisel.

Infection through a penetrating wound from a dirty conjunctival sac, producing panophthalmitis resulting in loss of the eye, may be a secondary complication. The conjunctival sac is particularly liable to be septic in the presence of a lacrimal mucocele. In all cases of extirpation of the lacrimal sac, and especially when this is performed preparatory to an operation involving section of the eyeball, I advise that both canaliculi be slit and their lining membrane destroyed with the galvano-cautery. I once lost an eye upon which I had operated for cataract; the eye became infected owing, I believe, to neglect of this supplement to the operation of excision of the lacrimal sac. The conjunctiva had been pronounced sterile by the bacteriologist after I had excised the sac preparatory to cataract extraction. When the eye suppurated after extraction the same bacteriologist found that it had been infected with a pneumococcus, one of the commonest and most virulent organisms lurking in a lacrimal sac mucocele. I have no doubt that the pneumococcus was lying low in the canaliculi, escaped the observation of the bacteriologist, and made its attack from this quarter upon the eyeball. The lesson is that the canaliculi should in all cases be dealt with at the same time as the sac.

Unfortunately every ophthalmic surgeon is only too familiar with the disastrous results which follow injuries inflicted with septic material. Suppurating cornea or panophthalmitis are frequently met with in farmers, road-menders, and masons, in whom a traumatic ulcer or a perforating wound has been produced by such septic material as the parings from a horse's hoof or by flying fragments of stone.

CASE 3.—Another case of traumatic cataract was that of a boy of 13, who was boiling fluid in a glass flask in a chemical laboratory when the flask burst. He only came under my observation at the hospital 17 days later, by which time a traumatic cataract in the left eye was present. There was a linear scar in the cornea running downwards and inwards; a posterior synchia of the lower pupillary margin was present, and a fragment of glass a few millimetres square lay on the anterior surface of the iris behind. The eye was not inflamed. The next day I removed the fragment of glass through a corneal incision. Six months later another small piece of glass revealed itself at the lowest point of the anterior chamber, and a third angular piece was cutting its way through the lower and outer part of the iris from behind. No doubt the movement of the iris membrane facilitated this. I removed the two pieces of glass through a corneal section. A month later an X ray examination showed that yet another piece of glass was wrapped up in the lens remains. At this date, with its pupil dilated, the eye, assisted by the appropriate lens, read 8/18, but with a small pupil no clear gap was available and 6/60 could not be obtained. Rather than risk displacement of this fourth foreign body into a more dangerous situation by needling the lens, I decided to leave matters as they were. There seemed but little chance of seizing the fragment, which was completely hidden. Many years later this eye remained harmless and quiet and presented a good appearance.

How so many fragments contrived to enter the eyeball, apparently through a single wound, is rather a mystery; naturally I expected but the one first apparent. It is to be presumed that a single large splinter broke into four fragments while in the act of penetrating the cornea.

CASE 4.—A lad of 17 years of age was cleaning an incandescent electric lamp bulb on Christmas Eve, 1903, when it burst, and a fragment of glass struck and penetrated his right eyeball, in this case through the sclerotic on the nasal

and within a few hours of his death, will talk cheerfully of what he is going to do when he is better. This state, the so-called *spes phthisica*, has been often described. But it must on no account be confounded with the state of resolution and hope with which, as I have mentioned earlier, some patients, particularly those whose mental life is healthily organised, face their trouble. This latter attitude is one to be encouraged; but the hope of the *spes phthisica* is far different. It does not make for recovery. It is almost tantamount to saying the patient has given up the struggle, and is of bad prognostic significance. And yet it should not be discouraged, for it does help the patient through his last days.

As I see it, the *spes phthisica* is a dissociation, the final stage in a long struggle, the initial one being, perhaps, evidenced in the man who refuses to acknowledge the diagnosis. The diagnosis and all it entails is so terrible that the individual cannot face the fact. It is pushed away more or less completely, and more and more completely as the disease progresses more and more. A number of patients, when in the middle stage, have described the "peculiar experience" of feeling that it is not they who are lying ill. They realise that they really are on the bed, and yet it does not seem to be them. They can adopt quite an objective attitude towards the rise and fall in their temperature, and towards their night sweats. Such things do not worry them in the least! . . . These are all stages, to my mind, in the dissociation which is so remarkable in its final form. In this interpretation of the phenomena, which I believe to be correct, I differ entirely from all the authorities I know on tuberculosis; but these authorities are, as a rule, authorities on the physical side only of the disease.

Summary.

1. Tuberculosis is a painless and long drawn-out illness.
2. There do not appear to be any specific psychoses or psychoneuroses connected with tuberculosis as a direct consequence of the disease. The abnormalities which arise, and they are many, are expressions of maladjustment such as may occur in any non-tuberculous individual.
3. The shock incident on diagnosis is great, and produces various anxieties and worries, not the least being the feeling that one is henceforth a pariah and an outcast.
4. The attitude the patient adopts towards his disease has a great effect on his progress. This attitude depends to no small extent on his sentiments, and on the way in which his sentiments are organised—the more ideal and the less self-centred the object of the sentiment the better.
5. *Spes phthisica* is a form of dissociation. In its initial stage it may be evidenced by a refusal to accept diagnosis; later the patient takes an objective view of his diseased body which seems to be something apart from himself; finally he is convinced he will soon be out and about again, the fact of his imminent death being absolutely dissociated. Prognosis in all these cases is probably bad.

NATIONAL COUNCIL FOR MENTAL HYGIENE.

The statutory annual general meeting of this Council was held on March 21st to receive the report for 1928-29. As the chairman, Sir Maurice Craig, remarked, the work has been steadily constructive rather than spectacular. Two successful series of lectures have been held and it is hoped that an educational series can be arranged for each spring and autumn. Although not strictly falling within the 12 months under review, reference was made to the remarkably successful conference held at the Central Hall, Westminster, last October (THE LANCET, 1929, ii., 998), and also to the international congress which is to be held in Washington next May. The full report of the London conference is now on sale (2s.) and a bulletin report of the Washington conference will be published as soon as possible. Propaganda work advances steadily; many drawing-room meetings have been addressed by members of the committee, and the Council hopes to organise a provincial campaign this summer. The subcommittee on the prevention and early treatment of mental disorders had done enough work to put it in a position to act promptly when the Mental Treatment Bill was rather unexpectedly introduced into the House of Commons this session. Many of the suggestions made by the committee have been incorporated in the Bill. This subcommittee has also circularised local authorities setting out the need for improved facilities for the treatment of poor persons suffering from minor mental disorders. The circular has been sympathetically received, and the Council propose to follow it up by sending an expert to discuss ways and means with the bodies and officials concerned. The subcommittee on the care, after-care, and treatment of the insane has done useful work in visiting observation wards of infirmaries; its report is expected to be very valuable in view of the changes in the poor-law. The subcommittee on mental disorders is investigating the problem of the sterilisation of the unfit, and is

addressing letters to scientific bodies and public organisations asking for their views on the prevention of mental disorders and defects. Useful work is also being done on the children's courts, and a memorandum has been sent to the committee which is inquiring into the working of these courts. As the result of a successful dance organised last winter, the Council now has a respectable balance at the bank. Pioneer work of this kind, however, is always in need of larger funds and more adherents if its progress is not to be crippled. The system of associate membership with an annual subscription of only 6s. makes it possible for everyone to participate in this essential national work.

HOLOPHANE OPERATING TABLE LIGHTING.

The makers of the ideal operating table lamp to which we called attention recently in an annotation (Dec. 28th, 1929, p. 1377) are Messrs. Holophane Limited (Scientific Illumination), of Elverson-street, Vincent-square, London, S.W. This unit was fully described at the December meeting of the Illuminating Engineering Society, and a full-size model of the unit, arranged with an operating table and other hospital accessories, is on view in the demonstration room of Messrs. Holophane Limited, where it may be inspected at any time.

APRIL CAMPAIGN AGAINST JUVENILE TUBERCLE.

The National Tuberculosis Association is planning a campaign for the month of April throughout the United States of America on the subject of childhood tuberculosis. The purpose is to emphasise the importance of treatment in the period of latency. No treatment is to be offered through the Association, however. It will confine its efforts to education. In connexion with this a pamphlet of diagnostic aids has been prepared and will shortly be available through State and local associations. It is illustrated by coloured plates of the tuberculin reaction and with excellent aquatone reproductions of X ray plates. Emphasis is laid on the paucity of symptoms—that a child with active tuberculosis may be above weight and free from cough or fever. Physical signs may be lacking. "A roentgenogram is indispensable in the examination of a child's chest." Children with diffuse pulmonary infiltrations should not be subjected to tonsillectomy and in no case of childhood tuberculosis should competitive sport be allowed. There is great danger that excessive strain may reactivate dormant infection. Besides this booklet, evidently designed for the use of physicians, a number of brightly coloured posters have been designed. Advertisements will appear in magazines and newspapers. Motion pictures are available. All this is made possible by the sale of Christmas seals at one cent each.

Births, Marriages, and Deaths.

BIRTHS.

CARMICHAEL.—On March 29th, at East Heath-road, Hampstead, the wife of Dr. E. Arnold Carmichael, of a son.
MATSON.—On March 23rd, at Farnborough Park, the wife of R. O. Matson, M.R.C.S., L.R.C.P., of Woking, of a son.
MELVILLE.—On March 20th, at Teak-Penn, Stockingstone-road, Luton, the wife of Dr. H. R. Melville, of a son.

MARRIAGES.

FOX—McDOUGALL.—On March 27th, at Christ Church, Wallington, Surrey, Theodore Fortescue Fox, M.A., B.Chir., son of Dr. and Mrs. R. Fortescue Fox, Beechshade, Beaconsfield, to Margaret Evelyn, elder daughter of Dr. and Mrs. W. Stewart McDougall, Benlloyd, Wallington.
RAMAGE—MOLLER.—On March 23th, at St. Andrew's Church, Much Hadham, Herts, John Steven Ramage, M.B., Ch.B., F.R.C.S.E., to Mary Muriel Moller, M.B., B.S.
SIMPSON—NICOL.—On March 31st, at St. Giles-in-the-Fields, London, Dr. J. E. A. Simpson, of Southampton, to Dr. Janet C. Nicol, of Keith, Banffshire.

DEATHS.

DIXON.—On March 30th, at Jamaica-road, Bermondsey, John Dixon, M.D., J.P., aged 97.
HAYES.—On March 28th, at Ecclesfield, Clyde Longman Hayes, M.R.C.S., L.R.C.P., Edin.
HICHENS.—On March 29th, in a nursing home in London, Peverell Smythe Hichens, M.A., M.D., F.R.C.P., of Havelock House, Guernsey, aged 59.
MACKAY.—On March 30th, at a nursing home at Broughty Ferry, John Yulo Mackay, M.D., LL.D., Principal of University College, Dundee.
WOODFORD.—On March 31st, at Wolverton Mansions, Ealing Common, Alfred Pownall Woodford, M.R.C.S., aged 78.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

on them the site of a foreign body as intra- or extra-ocular. The figures supplied by the radiologist were the three measurements of the site of the foreign body, vertically, horizontally, and posteriorly, in reference to the central point of the cornea. That such exact practitioners as ophthalmic surgeons should have been in the habit of using in combination only two at a time of the three measurements given is hardly to be believed. Yet so it was, and at a time when in military surgery large numbers of penetrating wounds of the eyeball were being met with, supplemented by those sustained by workers in arsenal and munition factories, I pointed out the grave error we were making. The following is a quotation from my paper¹ :—

"Let us suppose from the X ray examination that the foreign body is 7 mm. below, 5 mm. to the temporal side of and 9 mm. posterior to the centre of the cornea. On Chart I., ruled to scale in millimetre squares, we count 7 mm. downwards from the corneal centre A and reach the point B; we then count from B 5 mm. to the temporal side and reach the point C [Fig. 7]. As far as this diagram is concerned we conclude that the foreign body is intra-ocular, but it must also be within the limits of the globe, as outlined in the antero-posterior section, before the point is finally settled. We proceed to determine its position on Chart II., and again we count 7 mm. vertically downwards from the anterior pole reaching the point B, and then 9 mm. horizontally backwards and we arrive at C', and again find that the foreign body is located within the confines of the eyeball. I am assuming that Chart II. represents a vertical antero-posterior section, as it is usually taken to do.

"Now it is obvious that C' cannot be the true position of the foreign body, for we are representing it on a mid-line section, and we know that it lies 5 mm. to the temporal side of this section. Moreover, to determine the relative position of two points in space involves the use of three co-ordinates, and though supplied with the three required we are using but two of them at a time.

"Wherein then do we go wrong? Making use of our charts again, what we have to do after marking out A B, 7 mm. and B C 5 mm., is to draw the line A C, and determine its length. A B C being a right-angled triangle, this is an easy

FIG. 7.

Chart II Chart I
Illustrating incorrect method of using charts for plotting a foreign body.

proposition to solve, for $AC^2 = AB^2 + BC^2$, i.e., $AC^2 = 49 + 25 = 74$, and $AC = \sqrt{74} = 8.6$ mm. approximately. Now Chart II. is to be taken as an antero-posterior section of the eyeball, through its poles but cut in the oblique plane A C, and on it from the central point of the cornea we have to count down not 7 mm. and find the point B, but 8.6 mm. when we reach the point C; from this point we count backwards 9 mm. and if the spot arrived at, D, is within the limits of the globe, as outlined in the diagram [Fig. 8], the foreign body is truly intra-ocular. It will obviously appear in the chart whether intra- or extra-ocular, for the chart represents a section in the plane in which the foreign body lies.

"It is easy to show that we may arrive at a conclusion which might be disastrous to a patient, unless we do our work correctly.

"Let us revert to our previous example with this single difference—viz., that we will now assume the foreign body is reported to be 4.5 mm. posterior to the central point of the cornea, instead of 9 mm., the other measurements being 7 mm. downwards and 5 mm. to the temporal side, as before.

"If, using Chart II. incorrectly in the way in which it has hitherto been employed, we count 7 mm. downwards

and 4.5 mm. backwards we find the foreign body is located in the most dangerous part of the eyeball—namely, the ciliary body—but if, using our charts correctly, we regard the antero-posterior section (Chart II.) as one cut on the oblique plane A C and count, as we should, 8.6 mm. downwards and 4.5 mm. backwards, we find the foreign body is lodged harmlessly

FIG. 8.

Chart II Chart I
Illustrating correct method of using charts.

on the surface of the sclerotic, over the posterior part of the ciliary body, and is really extra-ocular."

To avoid the use of arithmetic and facilitate calculation, new and more accurate charts are now in use (Fig. 9). On the "en face" chart are ruled circles centred on the central point of the cornea and of radii 1, 2, &c., up to 12 mm. The length of the line A C is by this means automatically determined by these circles, and the correct site of the located foreign body is readily and accurately plotted. It appears to me that Gonin's very ingenious method for deciding, on the eyeball, the diameter on which an observed hole in the retina lies, might well be used in dealing with intra-ocular foreign bodies situated in the vitreous chamber. With this addition to our radiographic measurements and charts, our hopes for the successful removal of non-magnetic foreign bodies through scleral incision should be decidedly improved.

Correct plotting of the position of a foreign body in relation to the central point of the cornea is well illustrated by the following case.

CASE 6.—Captain X sustained an injury to his left eye by a pellet of No. 6 shot on Oct. 6th, 1917. I saw him eight hours after the accident. There was considerable subconjunctival ecchymosis. The pellet had produced a dent in the sclerotic on the outer side behind the ciliary region, but the tension of the eye was normal and no vitreous was exuding. With the ophthalmoscope, after use of a mydriatic, no track of any foreign body could be seen in the vitreous, which was free of haze and of hæmorrhage, but the retina was almost everywhere grey from concussion cedema. This cedema had diminished two days later, but was still present at the centre and to the outer side. One or two spots of hæmorrhage were now visible in front of the retina and extending far forwards into the lower part of the vitreous. Radiographic examination revealed a pellet in the position indicated by the accompanying charts (Fig. 10); which showed the foreign body to be extra-ocular. Had the same measurements been employed as formerly the inference would have been that it lay within the eyeball. As a matter of fact, though the sclerotic had been struck, it had not been penetrated by the pellet, which indeed I removed from the orbital tissues. The intra-ocular changes had been produced by concussion. The hæmorrhage gradually absorbed; the retinal cedema resulted in the formation of some yellowish-white dots arranged in an arc outside the yellow spot region, and these were still present when I examined the eye some six or seven years later. In the lower periphery near the site of impact some slight pigmented changes in choroid and retina were also permanent. There was never any displacement of retina, and the direct vision of the eye, corrected for its myopia, recovered to 6/9.

TRAUMATIC TUMOURS OF THE IRIS.

I come now to a rather infrequent sequela of a penetrating injury—namely, the formation of a cyst in the aqueous chamber.

CASE 7.—On July 29th, 1912, I excised an iris prolapsed through a wound at the highest point of the limbus of the right eye. The injury had been inflicted by a missile,

possibly a screw, thrown at a boy 17 years of age, a few hours before he was brought to me. A neat upward coloboma of the iris was the result of my operation, and vision was unimpaired. On July 10th, 1916, my patient was serving as an officer in France when the same eye gave trouble after receiving a further slight injury with a twig, and Sir William

FIG. 9.

Charts now employed at Moorfields.

Lister recognised a cyst of the iris. On August 26th, 1915, I punctured the delicate grey wall of a cyst of the iris lying at the bottom of the anterior chamber. The cyst was somewhat lobulated and its anterior wall was slightly pigmented. The cyst collapsed, but a month later it was obviously re-forming, and on Oct. 27th, 1915, I made a section downwards with a Graefe's cataract knife, punctured the cyst in doing so, and performed a small iridectomy downwards, through both anterior and posterior lamellae of the iris tissue. Five weeks later I had to deal with a small knuckle of iris pillar prolapsed through the section; I removed the knuckle and covered its site with a flap of ocular conjunctiva.

The eye did well, but was now the subject of a double keyhole pupil. Though it was highly astigmatic from distortion of the corneal curvature, it could read 9/8 with the help of the appropriate cylinder lens. In this condition it remained permanently; the patient resumed his active war service, and was last seen by me in 1924. At this date a residue of the cyst wall remained and presented the appearance of a bracket at the bottom of the anterior chamber; the temporal horn of the bracket showed definitely some pigmented iris tissue. The nasal horn consisted of a remnant of the grey cyst wall and was devoid of any avascular pigment.

Traumatic tumours of the iris arising from implantation of epithelial cells are of two kinds. If corneal epithelium is carried into the iris the implanted epithelium proliferates, the central cells of the tumour—at first solid—degenerate, and a cyst is formed, the wall of which consists of stratified epithelium. The fluid contents are either serous or slightly turbid, and the iris membrane is often split by the cyst into two layers, of which the anterior is usually thinner than the posterior. Cysts of similar origin and construction have been described in the cornea. Another form of implantation tumour of the iris is the solid epithelial pearl tumour. This consists of epithelial cells, together with fat, sebaceous matter, and cholesterol crystals; the contents in time may become somewhat liquefied. This form of tumour arises from an eyelash, or from the cells of the root sheath of an eyelash which have been implanted in the iris tissue by the perforation. It seems unlikely that the cyst in the case I have just narrated belonged to either of these two classes. Remnants of implanted cells were certainly left behind by me in the iris tissue, and had these cells been epithelial further proliferation should have taken place. This did not occur, and I conclude that my case belonged to a third class of iris cyst—namely, the anterior chamber cyst with endothelial cell wall. Cysts of this class present clinically much the same appearance as the epithelial implantation cysts; their walls are transparent and their contents clear fluid. They are attributed to obstruction in the mouth of a crypt in the iris membrane, whereby lymph is retained, and they have been repeatedly observed to form after a penetrating injury, though they may occur without any trauma. It has been

suggested that endothelial cells are carried in from the back of Descemet's membrane and may possibly play a part in the cyst formation in the cases preceded by penetrating injury. This form of cyst, a retention cyst, is likely to be permanently cured by simple puncture or generous excision of its wall, as happened in the case I have reported.

It will be seen, therefore, that when an eyelash has been carried into the anterior chamber by injury—and is seen lying upon the iris, it is important to remove it. This is a remarkable but not a very rare occurrence. To remove a lash from this situation is not always quite as easy as would be imagined. Attempts to grasp it with a forceps introduced after a keratome section usually result in the iris belling up, so that this membrane is seized simultaneously with the lash in the branches of the forceps. I have found it simpler to pass a curette, with its groove directed anteriorly, over the iris and behind the lash, through a suitably placed section. A flexible Tyrell's blunt hook can then be guided in the groove of the curette behind the lash. The lash, macerated and pliable, can readily be engaged at its middle by the hook and withdrawn from the anterior chamber doubled upon itself; the difficulty which the iris membrane otherwise offers is thus readily overcome.

Siderosis.

The degenerative changes which occur in an eyeball in which an iron fragment has been retained over a long period are known as siderosis and result in degeneration of the eye. An iron-containing pigment is deposited in the tissues and particularly in the retina, pars ciliaris and pars iridis retinae and in relation to the lens capsule. Much argument has waged as to whether this pigment is derived from the retained foreign particle or is of haematogenous origin. Widespread green staining appears in the tissues of an eyeball which has harboured a particle of copper, a metal which, by the chemical changes which it will undergo, is universally recognised as

FIG. 10.

Illustrating site of foreign body in Case 6 plotted correctly on improved chart.

most destructive when it is retained within the eye. Such green pigment is certainly not haematogenous, and comparison of the two conditions leads to the inevitable conclusion that in siderosis the iron-containing pigment is derived not from the blood but from the retained foreign body.

A TRANSPARENT LIVING LABORATORY.

The development in eyes of implantation growths, solid and cystic, is a reminder that the pathological processes with which the ophthalmic surgeon has to deal are identical in origin with those experienced in other parts of the body; in every structure the result will be modified by and adapted to the soil in which the process develops, but in the eye alone can the development be viewed directly by the observer. I have with the ophthalmoscope watched a patch of solitary tubercle manifest itself in the choroid, and absorb and resolve into a scar under the influence of tuberculin injections. In the eye we may watch

syphilitic processes develop and subside under treatment. Inflammatory processes from direct or indirect microbial implantations or from great varieties of toxæmia come under our notice. Gas gangrene occasionally proceeds under our eyes. Pathological processes produced by organic and inorganic poisons are well known to the ophthalmic surgeon. Blood and vascular disorders are watched in the retina, which is only a detached portion of brain tissue. The organisation of fibrous tissue in relation to blood-clots can be observed in progress. Slit-lamp observation has added to the resources which the ophthalmoscope supplies. We frequently have opportunities to study primary malignant growths, both of epiblastic embryonic cells in connexion with the retina and of mesoblastic cells with the choroid, while secondary metastatic deposits are not uncommon.

The eye is a transparent living laboratory in which more work, both experimental and clinical, might perhaps be done by the research worker and the expert pathologist. In no other tissue of the body can we so closely relate the post-mortem finding to the observed living process. The tendency of the age is towards scientific medicine. How much of this is real scientia? Does it not tend to grow top-heavy, based too much on hypothesis? How much do we see accepted and discarded by our profession in a single life-time? Hypothesis is a necessary aid in prosecuting research, but, until proved to be fact, is no sure foundation for the practice of medicine and surgery.

PARAPHARYNGEAL ABSCESS.

THE QUINSY THAT ISN'T.

BY E. WATSON-WILLIAMS, M.C., CH.M.,
F.R.C.S. EDIN.,

SURGEON IN CHARGE, EAR, NOSE AND THROAT DEPARTMENT,
BRISTOL ROYAL INFIRMARY.

To many medical men has probably fallen the humiliating experience of incising a "quinsy" and entirely failing to locate the pus; and this even where the history, symptoms, and fever have made the operator confident that "it was ripe," though perhaps the local appearances have been somewhat anomalous. As a rule, within a few hours or at most a few days the abscess is spontaneously evacuated. A closely similar occurrence is the bursting of a "quinsy" that the medical attendant has just assured the patient is not ready for incision. In both cases the volume of pus makes the error somewhat puzzling, and it is perhaps significant that the patient usually says, "it burst in the throat." The explanation, I venture to suggest, is in many cases that the abscess is not a true peritonsillar collection at all—that is, situated between the capsule of the tonsil and the sinus tonsillaris—but lies posteriorly in the lateral wall of the pharynx. Such an abscess is sometimes described as "peritonsillar but behind (or external to) the tonsil" instead of in the customary position above it. Though unusual, true peritonsillar abscesses are found in these situations. But the condition now under discussion is a suppuration in the bucco-pharyngeal aponeurosis behind the palato-pharyngeus muscle and posterior faucial pillar. It tends to point in the pharynx about the level of the lower pole of the tonsil, in the potential gap between the palato-pharyngeus muscle in front, the lower border of the superior constrictor above, and the stylo-hyoid ligament (with the middle constrictor) behind. These relations can generally be made out at operation: cases such as (1) and (3), where the tonsil was removed, demonstrate that the abscess is not peritonsillar. I have twice been able to verify the position of the opening in cases of spontaneous evacuation. This condition has clinical features that distinguish it from peritonsillar abscess. It deserves to be classified as a separate entity, if only because a

special line of treatment is required, and I prefer to describe it as parapharyngeal.

Clinical Features.

The age and sex of my patients since 1925 were:—

M. 13 (d), 20, 23, 28, 30 (d).

F. 25, 26, 30, 32, 32, 35, 46 (t).

Five of the patients gave histories of previous quinsies, for which one had had the tonsils removed. In two more the abscess followed dental extraction without tonsillitis (d. d.) and in another (t) it resulted from a vigorous but vain probing search for a fish-bone.

In a typical case the onset closely resembles that of quinsy. The patient, a young adult, often "subject to tonsillitis," has an acute sore-throat. Instead of resolving, this persists, with unilateral pain, dysphagia, difficulty in opening the mouth, and swelling deep in the neck between the angle of the jaw and the hyoid. The temperature ranges to 100° or 102° F., the breath is foul, and the tongue coated, and there is constipation. In a severe attack the patient may be much distressed.

On examining the throat (not always an easy task) the tonsil of the affected side is seen to be pushed inwards and often apparently enlarged. The striking feature is the absence of œdema of the mucosa of the soft palate and uvula; this œdema is a constant accompaniment of a true peritonsillar abscess, except in the very first hours, and often suffices to hide the tonsil, even when this is swollen and pushed inward. Closer inspection in parapharyngeal abscess shows that the tonsil is conspicuous, both on account of its displacement and because it is rotated forward so that we see the inner surface. If the attack began with tonsillitis there may be traces of this remaining, but neither anterior faucial pillar nor uvula is appreciably swollen. The posterior pillar is displaced inward more than the tonsil itself, and behind it the lateral pharyngeal wall bulges so that the recess is obliterated. In this region the mucosa appears œdematous, particularly if the tongue is well depressed to give a low view. The tonsil is usually not even tender on pressure, but the posterior swelling is boggy and often exquisitely sensitive; low down in it an area of pointing may be palpable.

Corresponding with the absence of palatal œdema, the voice has not the muffled tone so typical of quinsy. The cervical swelling tends to be more considerable than is usual with quinsy and is often rather a deep boggy infiltration than an adenitis, though the latter may coexist; the area tender to deep pressure is more extensive than we should expect. The dysphagia also is apt to be more severe than with quinsy, where only the worst cases are completely unable to swallow. Here this symptom is not uncommon, and seems out of proportion to the throat appearances. The patient may have to lie on one side to avoid constant disturbance from saliva overflowing into the trachea. When by an effort he can swallow fluids, he soon finds that *c'est le premier pas qui coûte*—the first gulp is the painful one. An occasional "long drink" is consequently much preferred to frequent sips.

In addition to pain on swallowing there may be constant aching in the side of the throat and neck. It does not as a rule radiate to the ear, as with quinsy, but may be sufficiently intense to need full doses of opium. Difficulty in opening the mouth is not due to trismus but to the neck infiltration and the pain of muscular activity; the patient may be able to open the mouth with the hand when he cannot in the ordinary way. Pain of all sorts tends to diminish as the abscess begins to point. In those cases where I have been able to secure pathological examination of the pus a streptococcal infection has been reported.

Diagnosis and Course.

Diagnosis rests on the manifest signs of suppuration in the region indicated, and differentiation from a true peritonsillar abscess on the features just enumerated, especially the absence of palatal œdema. With a tonsillar or with a true post-peritonsillar abscess there is a recess behind the posterior faucial

pillar, though this may be difficult to determine until the patient is anaesthetised. Retropharyngeal abscess is rare after the fourth year; it lies behind the pharynx, though usually not in the mid-line, and cervical adenitis is not a conspicuous feature. The signs of suppuration should prevent confusion with a gumma or neoplasm, though many sarcomata of the tonsil have been incised in error.

The abscess tends to point in the pharynx and in many cases ruptures spontaneously. Unless relieved by nature or art, suppuration may extend into the deep cervical planes with disastrous results. Septicæmia, mediastinitis, jugular thrombosis, and even erosion of the internal carotid artery* have all been recorded in circumstances that leave no doubt that an abscess of this type was involved. In my own series there have been no serious sequelæ, but all these cases opened or were opened into the pharynx. Laryngeal oedema probably need not be feared, though it is in the post-peritonsillar type that it is apt to occur.

Treatment.

In view of the grave possibilities the abscess should be opened as soon as the surgeon feels there is pus present. A general anaesthetic is necessary, and for this nothing is so suitable as ether given by the open drop method. Before the anaesthetic is started a gag (e.g., Sydenham's) should be placed between the patient's teeth, or at least a "mouth-opener"; Killian's "long speculum for median rhinoscopy" is excellent. As with all such operations, a tracheotomy set should be ready. For those who like it, an aspiration pump may be useful. The patient should be arranged so that the head can be readily and rapidly lowered in case the abscess ruptures during induction. With the head fully extended, so that the vertex is downward, the mouth is well opened. The swelling is palpated and as a rule an area of pointing can be made out as described; the abscess is then opened in that area, or, if it is not felt, at the spot mentioned—viz., immediately behind the posterior faucial pillar at the level of the lower end of the tonsil, directly outwards or a trifle forwards. For opening the abscess only a really blunt instrument is permissible. I generally use a very blunt tracheal dilator; when closed it readily penetrates the softened mucosa and can then be opened in a longitudinal direction to give free exit to the pus. Once when this was not available a tongue depressor served perfectly, and on three occasions the gloved finger-tip has sufficed. A really blunt instrument can be passed outward without fear if pus is not struck at once, as it generally is; a narrow or sharp instrument could not be used thus.

After-treatment presents no special features. The patient may find a difficulty in opening the mouth properly for some days or even weeks, owing to the infiltration of the muscles, especially, it would seem, the digastric; he should be encouraged to exercise this function often, stretching the mouth to maximum gape two or three times in succession several times a day.

Where the abscess is not opened by the manoeuvre described it must be approached from without. An incision along the anterior border of the sternomastoid will give excellent access. The digastric muscle being retracted backward, the area is approached a short distance above the hyoid bone and behind the margin of the hyoglossus. The operator should be prepared to deal with bleeding from the large vessels, which are sometimes exposed in the abscess cavity, but the line of approach just indicated lies far enough in front to avoid creating trouble that is not already present.

Case Reports.

CASE 1.—A man of 20. His medical attendant told me that tonsillitis had started 10 days before. On the eighth day, feeling certain that there was a peritonsillar abscess, he had incised the palate above the right tonsil and had explored the tissues with Sir St. Clair Thomson's quinsy forceps, but without result. He had waited in daily expectation of

spontaneous opening until the fifth day from then (thirteenth day of the disease). Difficulty in swallowing and in opening the mouth had become severe, and he made a second incision and exploration but with no greater success; both operations had been done under general anaesthesia. On examination, which was considerably hampered by pain in opening the mouth, the tonsil was seen not to be swollen, but to be pushed forward by a large swelling of the lateral pharyngeal wall. There was no oedema of the soft palate or uvula and the incision was healing; but a deep cervical infiltration present for some days was now conspicuous and brawny. Under general anaesthesia the tonsil was dissected out very easily, but without revealing the abscess. The pharyngeal swelling was palpated, and behind where the lower pole of the tonsil had been the examining finger passed easily through an apical swelling of the submucous tissues, tearing the mucosa and evacuating a large and very offensive abscess. Two days later all symptoms had disappeared, except difficulty in opening the mouth, which persisted for a month.

CASE 2.—A woman of 34 came complaining of a sore-throat for four days with some difficulty in swallowing. She had once before had a quinsy. On examination I found the right tonsil pushed forward and inward, not swollen; there was no oedema of the mucosa of soft palate or uvula, but there was an obvious bulging of the lateral pharyngeal wall immediately behind the tonsil. A tender, ill-defined swelling could be felt deep in the neck behind the angle of the jaw; the temperature was 100° F. Treatment was by salicylates and external heat. Three days later the pharyngeal swelling was still more prominent, but no longer involved the posterior wall; there was no palatal oedema. The cervical swelling was larger and firm, with considerable dysphagia, and difficulty in opening the mouth; the temperature was 102.2° F. Under general anaesthesia the pharyngeal swelling was palpated, and an area found rather low down—i.e., distinctly further down than the lower pole of the tonsil—where instead of the general rather boggy firmness there was a palpable gap in the submucous tissues. A blunt tracheal dilator passed into this with very little pressure, and on opening it let out an ounce of rather offensive pus which liberated. Recovery took place in five days.

CASE 3.—A woman of 30 had several quinsies, and about two years ago I dissected out the tonsil. The month later she came to me with the story that she had got another quinsy; there had been pain in the right side of the throat for three days, with great dysphagia and difficulty in opening the mouth. There was no trace of tonsil, but behind the right posterior faucial pillar a large swelling was visible, pushing in the pharyngeal wall; the deep tissues of the neck were tender but not manifestly swollen; the temperature was 100° F. Shortly before operation, early next morning the abscess burst "into the throat," discharging a quantity of very offensive pus and bringing instant relief.

CASE 4.—A boy of 13 came complaining of pain in the left side of the throat and the left ear for six days; there had never been any previous trouble in either. Eight days before the onset a right upper molar had been removed but no abscess had been found under it. There was great difficulty in opening the mouth, and some dysphagia; the temperature was 102° F. On examination the left tonsil was seen to be pushed forward and also rotated forward by a swelling in the lateral wall of the pharynx behind the posterior pillar; the swelling caused some protrusion of the palate above the tonsil, but there was no oedema of the mucosa of the palate. Between the angle of the jaw and the hyoid a deep and tender swelling was found, apparently adenitis with much periaadenitis. Under general anaesthesia the pharyngeal swelling was palpated, but no area of softening was discovered. Gentle pressure with a blunt tracheal dilator in the usual site produced a gush of offensive pus. Two days later all symptoms had disappeared and the tonsil looked normal.

CASE 5.—A woman of 20 came complaining of sore-throat for eight days, at first bilateral, but during the last two days on the left side only, much more painful, and accompanied by swelling in the neck. For one day she had been unable to swallow anything. Four years before she had had a quinsy. On attempting examination it was almost impossible to open the mouth. When this was achieved, the left tonsil was seen to be red, conspicuous, and pushed forward and inward; there was no oedema of the palate. Below and behind the angle of the jaw was a deep, hard, and tender infiltration. The temperature was 100° F. Under anaesthesia the same evening the mouth was properly opened and a prominence of the pharyngeal wall immediately behind the tonsil was palpated. A "gap" was felt level with the lower border of the latter and the gloved finger-tip passed easily through the mucous membrane at this point, liberating about one ounce of very foul pus. Two days later all general symptoms had disappeared, and a week after the operation she was perfectly well.

CASE 6.—A married woman of 32 complained of sore-throat for six days, with some difficulty in swallowing. There

* Mayer, O.: Wien. klin. Woch., April, 1926, p. 508; Negus, V. E.: Proc. Roy. Soc. Med. (Sect. Laryngology), 1929, xxx, p. 516.

was some enlargement of the glands on both sides behind the angle of the jaw, and on the left the swelling was great, ill-defined, and very tender. The left tonsil was swollen and pushed forward by a swelling behind it, but there was no palatal oedema. Next day under general anaesthesia the swelling was palpated and found to be in the lateral wall of the pharynx; behind the tonsil was an area of softening and the gloved finger-tip opened an abscess. In six days she was perfectly well.

The following case was not under my care, but I had exceptional opportunities of observing symptoms and progress.

CASE 7.—A medical man, aged 30, had had the left lower wisdom tooth removed three weeks earlier for caries; there had been no abscess. The pain was not relieved but got steadily worse, and was felt behind rather than in the jaw. For three days he was unable to swallow saliva, and for one day could swallow nothing at all, nor could the teeth be separated except with the hand; sleep was obtained only with large doses of morphine. He sought a surgical colleague and asked him to open the abscess which, from his sensations, especially on movement, he located "deep to the hyoglossus at its posterior border." Incisions were made in the mouth along both sides of the jaw and the tooth socket was curetted, but without finding pus. Some relief followed, though opening the mouth remained difficult, but high temperature persisted and he looked and felt very ill. A consultation was held, at which the diagnosis of peritonsillar abscess was suggested, but he declined to accept this; the tonsil was not swollen or tender, there was no palatal oedema, and a swelling could be felt in the pharyngeal wall below and behind the tonsil. Six days after the operation he felt a tickling in the throat, and a large abscess opened rather gradually; the pus coughed up literally "stank the house out!" The opening of the abscess was discernible later, rather low down in the lateral wall of the pharynx. Though all other symptoms rapidly subsided, five weeks elapsed before he could open the mouth in the normal manner.

Summary.

(1) Parapharyngeal abscess resembles in its clinical features peritonsillar abscess; the most striking difference is the absence in the former of oedema of the palatal mucosa.

(2) The condition should be suspected when a "quinsy" appears to run an anomalous course, or when incision in the usual site above the tonsil fails to locate pus.

(3) The abscess tends to point low in the side of the pharynx behind the posterior faucial pillar; it is easily opened here by slight pressure with a blunt instrument, which alone is permissible.

A STUDY OF THE ANTIRACHITIC VALUE OF IRRADIATED YEAST.

BY STANISLAW K. KON, PH.D.,

AND

MIECZYSLAW MAYZNER, M.D.

With the Radiological Assistance of

HENRYK ADELFANG, M.D.

(From the Biochemical Department, State School of Hygiene, Warsaw, and the Municipal Home for Foundlings, Warsaw.)

As yeast is the richest known source of ergosterol a study of the extent of its usefulness after activation by ultra-violet rays deserves attention. As far as we are aware, A. F. Hess¹ was the first to test the antirachitic potency of irradiated yeast. He administered daily to rachitic infants "from 0.5 to 1 g. doses, suspended in milk. This preparation was readily taken and brought about . . . a definite curative process." The yeast was also tested on rachitic rats and caused calcification of the epiphyses when from 10 to 25 mg. were given daily. Smaller amounts were not tested. Though these preliminary observations were highly encouraging, the therapeutic possibilities of irradiated yeast have not since been given much

attention. Kirsch, in 1928,² described experiments on rats wherein good results were obtained; he used, however, very massive doses, from 0.5 to 1 g. per rat daily. Wachtel³ recently published a paper on "the increase and vitamin enrichment of mother's milk and cow's milk by means of irradiated yeast." It is stated there that "cenomilchquell," probably a commercial preparation, the composition of which is not given, "containing irradiated yeast as the most important and predominant component," is extremely effective in promoting the milk-flow of lactating mothers. The administration of irradiated yeast (amount not stated) to milch cows is said to have a very favourable effect on the quantity of the milk produced and its antirachitic value. Clinical results are not given but, according to Wachtel, the "yeast-milk" will be given a practical test this winter in a paediatric clinic.

One of us (S. K. K.) was interested for some time in the problem of ultra-violet activation of yeast and, during a visit to the United States a year ago, had the opportunity of discussing with Dr. Hess the therapeutic possibilities of such irradiated yeast. He was encouraged by the latter to try the yeast in Poland. This was mentioned by Dr. Hess in a recent paper⁴ and, though the conditions in our country with regard both to the severity of rickets and to the economic situation are not so hard as pictured by him, yet the cost of treatment will without doubt be of the utmost importance in deciding the issue of any large-scale antirachitic action in Poland. Reliability, low price, and ease of preparation are essential if an antirachitic product is to gain access to those classes of the population where rickets is common. Irradiated yeast seems to fulfil these requirements to a remarkable degree. According to Hess,⁵ "there may well be a field for this preparation, especially where the matter of expense is of primary importance. Activated yeast can be prepared at low cost and is sufficiently potent for all therapeutic purposes."

The present communication is the result of a coöperative investigation started by the State Institute of Hygiene in Warsaw in order to gather reliable experimental information on the practical value of this and other antirachitic preparations. It is of a preliminary nature, firstly because of the limited experimental data presented, and, secondly, because it covers only a small part of our scheme and leaves many important problems pertaining to irradiated yeast untouched. As we believe, however, that the results obtained are so far conclusive and reasonably accurate, we deem it advisable to publish this account.

Experimental Method.

Pure baker's yeast was used. It was always purchased fresh directly from the same reliable factory, brought immediately to the laboratory, and spread on paper until air-dry. It was then ground in a laboratory mill, and then in a ball-mill to an impalpable powder, and stored at room temperature in glass-stoppered jars. For activation the yeast was spread by means of a sieve in thin layers (50 g. on an area of 52 by 34 cm.) on metal trays and exposed to the radiations of a Hanan quartz mercury-vapour lamp (180 v. 7.5 a.) for 30 minutes. At the end of 15 minutes the layer of yeast was resifted, in order to expose a fresh surface to the action of the rays. No effort was made to exclude oxygen. After irradiation, 0.75 g. portions of the yeast were weighed out and sent to the children's home for testing.

The experiments were carried out on a group of 12 rachitic children, inmates of the municipal home, ranging in age from 4 months to 2½ years. Six of them were given irradiated yeast, three controls the same amount of non-irradiated yeast, while three other controls were kept on the institutional diet without any addition. In the course of the investigation all these children were kept under uniform conditions, partaking, according to age, of the diets usually employed in this institution. The experimental results are given in the Tables. The yeast was

administered once daily suspended in the milk mixture, and was readily taken. There were no gastro-intestinal disorders. The administration of the yeast was continued even in the presence of intercurrent illness associated with fever.

Calcification of the cranial bones was generally the first clinical sign of improvement, craniotables disappearing in the course of two to four weeks. This was followed by an increase of muscular tonus. Radiologically, advanced healing could be noticed in

the course of one month, while serum phosphorus (estimated by the Briggs-Bell-Doisy method) increased markedly within ten days. After about one month a difference in behaviour and activity between the two sets of children became quite noticeable, the soft-muscled, flabby, untreated babies contrasting with the playful, energetically kicking treated ones. The rapid rise of the serum phosphorus in the group receiving the irradiated yeast is noteworthy. In a few cases the phosphorus reached a rather high level,

but no untoward symptoms whatever were associated with this rise. The serum calcium was regularly estimated (by the Clark-Collip modification of the Kramer-Tisdall method). It remained quite normal throughout the experiment in the group of treated infants, though it was low in some of the controls. Routine examination of the urine disclosed a perfectly normal picture. There are no noteworthy differences in the weight increments of the two sets of children. We did not notice the temporary growth stimulus reported by Hess after administration of autolysed or irradiated yeast to infants. Our dosage (0.75 g. daily) is based on the amounts given by Hess and also on a rough calculation of the possible activity of the yeast. It seems to be adequate. We are studying now the effects of higher and lower concentrations.

A commercial preparation of irradiated yeast has lately been widely advertised in America, the hope being expressed that with the addition of the antirachitic vitamin D this particular brand of yeast "will play an increasingly important part in the American dietary." We doubt whether the inclusion of such a potent preparation in the daily menu would be wise or advisable. The recent work on hyper-vitaminosis, and especially the important findings of Jundell,⁶ should sound a serious warning against the indiscriminate use of irradiated preparations and foods by the general public. Antirachitic medication and prophylaxis must be left in the hands of physicians.

Summary.

The daily administration of 0.75 g. of irradiated yeast to rachitic infants brings about a disappearance of the symptoms in the course of six to eight weeks.

THE MECHANISM OF A MEASLES EPIDEMIC.

By PERCY STOCKS, M.D., D.P.H. CAMB.,

READER IN MEDICAL STATISTICS IN THE UNIVERSITY OF LONDON,
AT THE GALTON LABORATORY, UNIVERSITY COLLEGE.

EVERY alternate year the educational and health authorities of London prepare to receive the attack of measles, destined to make about one hundred thousand children miserable, to say nothing of their parents, to kill more than a thousand of them, and to leave many more with health impaired for life. In facing this periodic attack there is brought into play a great deal of administrative machinery, without, it is to be feared, producing any sensible effect on the course of these epidemics, though certainly ameliorating their toll of mortality and crippling disease. It is a little puzzling that we are content to gaze upon this spectacle, which has been going on not only in London but in every large city for centuries, without troubling very much about its cause, whereas mathematicians readily devote their lives to working out with the utmost precision the causes which determine the periodic return of planets and comets, which do not seem to have any remarkable relation to our happiness, interesting though they are.

The solution of problems such as the causation of epidemics are left to a few underpaid and overworked research workers who have ideas as to how the problems might be solved but neither funds nor adequate assistance by which to even collect the available information. Much, indeed, of the desired information is found not to be available, since the

notification records, secured at considerable public expense, are considered to have served their purpose when the necessary administrative action has been taken, and have been sent to the destructor. This is not surprising, because the medical officers in our public health services certainly have no time for prolonged and arduous researches into such matters. And so these epidemics come and go with monotonous regularity whilst every ten or twenty years some research worker in vital statistics finds time to take up the problem where a predecessor had been compelled to leave it, and advances matters one stage further towards the desired solution. Such is our English method of "muddling through."

Cause of Periodicity.

In a paper published in October, 1928,¹ I showed, from analysis of the records* of some 10,000 measles cases and their contacts in St. Pancras, that if immunity to measles can only be acquired by an attack of the disease, the periodic changes which actually occurred in the proportion of children not immune in that sense in the total population at different ages during the years 1924-28 were much too small in amplitude to account for the epidemic phenomena during those years.

In the upper portion of Fig. 1 (which is a modification of Figs. 4A, 4B, and 5 in the paper referred to) the fluctuations in the actual total numbers of children under 10 who had become insusceptible owing to a previous notified attack are shown. As an example of the amount of fluctuation which really occurs I may quote the conclusion that at the pre-school ages 2, 3, and 4 the 1926 epidemic brought down the percentage of children at risk from 86 to 76, at the infant school ages 5 and 6 from 71 to 61 per cent., and for all children under 10 from 74 to 67 per cent., or in actual populations from 20,500 to 24,000 out of 30,000 in all.² Allowance for the fact that all these figures are slightly too high, owing to 10 to 15 per cent. of cases probably escaping notification, does not appreciably affect the conclusion that the amplitude of these fluctuations, which has usually been assumed to be sufficient to account for the biennial periodicity of measles epidemics, in actual fact does not suffice to explain this. A rapid calculation from Fig. 4 leads to the conclusion that about 21 per cent. of all children of the school ages 5-13 would be at risk to measles at the start of an epidemic and about 18½ per cent. at the end of it.

If, however, we could suppose that, as for diphtheria, each measles case was accompanied by several latent cases but that the latent immunity so produced gradually disappeared after the epidemic, as Gill³ has shown to occur in malaria, taking about two years instead of five years to disappear, then the amplitude of these immunity waves might be increased 3, 4, or 5 fold and we should have a most reasonable explanation, not only why the epidemic comes to an end but why it fails to occur in the next year when the seasonal conditions are favourable and there are plenty of children available who have not had the disease†

Suggestions of Latent Immunisation.

I was not aware that any previous suggestion of a latent immunisation in measles had been made when I produced evidence in favour of it in the paper referred to, but I find that as early as 1913 Butler, in a remarkably able paper on measles to the Epidemiological Section of the Royal Society of Medicine,⁴ suggested, though he was not able to prove it, that "not age, per se, but the opportunity which it confers of acquiring an active immunity through exposure to attenuated or minor doses of infection brings about the changes in susceptibility

* Made available for research through the kind coöperation of the Medical Officer of Health, Dr. G. Sowden.

† According to the calculation in St. Pancras, in November, 1926, 51.6 per cent. of children aged 5 to 10 had not had measles as compared with 53.8 per cent. in December, 1925, when a large epidemic followed.

exhibited..." Dudley¹ called attention again to this statement of Butler's in a paper read to the same section a year ago, and pointed out the similarity between the Willesden curve of incidence amongst

show so well the rapid loss of congenital immunity during the first year. The maximal age in the St. Pancras curve is not attained until two years later than in the Willesden curve, but the maximum reached

FIG. 1.

contacts and the immunity curve in diphtheria according to the Schick test.

In Fig. 2 I have brought together on the same diagrams curves constructed (A) from Butler's series of histories of measles in Willesden school-children, and (B) from the St. Pancras notification data. The left hand portion of the figure shows the percentages of children who had at some time passed through a clinical attack at successive years of age up to ten and indicates a similar trend in both, but somewhat lower percentages throughout in St. Pancras, owing to notification being not quite complete, and Butler's data being restricted to public elementary school-children. The curve B (1) represents the condition of affairs at the start of the 1926 epidemic, B (2) a year later, and B (3) a year previously, when no epidemics followed, and the difference between these is clearly too small and inconstant to determine

is practically the same, about 90 per cent. To produce this effect on the curve and thus reduce the mortality has certainly been the aim of public health authorities in recent years, but much as I would like to attribute the difference to these efforts, it must be admitted that it may perhaps be due to other causes such as different housing conditions and degrees of overcrowding in the areas compared. A comparison of the B (4) and B (5) curves shows that in the second and third years of life the expectation for a child who has not had it of catching measles during an epidemic is increased six-fold if a case occurs in the same house, or at ages 4, 5, or 6 it is increased five-fold. The percentage attack-rates in the 1926 epidemic were as given in Table I.

The chance of infection among contacts living in the same house cannot be much affected by school attendance, at any rate up to the eighth year, since

TABLE I.

Age-group	0-	1-	2-	3-	4-	5-	6-	7-	8-	9-
Contacts at risk (B1)	59.0	75.5	73.1	80.5	88.4	91.9	82.1	75.3	61.4	56.2
All children at risk (B5)	8.5	12.1	12.9	15.0	17.7	18.8	16.7	6.5	2.9	1.5
Ratio of B5 to B1	0.144	0.160	0.177	0.186	0.200	0.205	0.204	0.086	0.047	0.026

the occurrence or non-occurrence of epidemics in alternate years. The right hand portion of the figure compares (A) the attack-rates at each age in Willesden during 1908-11 among the children still at risk living in the same house as a case, with (B (4)) the same in St. Pancras during the 1926 epidemic, and at the foot we have (B (5)) the attack-rates during the same epidemic in the whole population at risk in St. Pancras. The apparent difference between the upper curves in the first year of life is merely due to Butler having subdivided this age-group into two halves, whilst any point represents the whole year, and does not

contacts are kept at home from school in any event, and the B (4) rates may therefore be taken as units for the measurement of immunity at each age, and the B (5) rates in all children at risk expressed in terms of these units should indicate how the expectation of catching measles from any source whatever changes with advancing life. It appears that this ratio increases up to age 4, as would be expected from the ever-increasing range of movement of the child, but strange to say it remains steady from 4 to 6, and then falls off, so the expected increase in risk at age 5 does not appear, and I think that

Butler was well justified in giving a hesitating support to his statement that "delaying the age of commencing attendance at school would probably raise to a higher age the proportional incidence of measles." In whooping-cough, in which disease, as I hope to show in a paper shortly to be published, latent immunisation seems to be absent or of little importance, the ratio of attack-rate in all susceptible children to attack-rate in susceptible home contacts increases from the second year of life to double its value by the fifth year, and continues to increase steadily afterwards, and I think there is no doubt that the different behaviour of the ratio in measles, ceasing as it does to increase by the fifth year and actually decreasing after the seventh, can only be explained by latent immunisation counteracting the effects of increasing mobility and risk of infection.

Having read rather hastily Halliday's admirable report on the incidence of measles in Glasgow tenements⁶ published in 1928, just before my original

tiousness during period t is measured by the ratio $p=s/n$; and if q be the ratio during a post-epidemic period of low incidence, then the index of apparent infectiousness is p/q . That is to say, it is the chance of one case being followed by another in the same house under standard conditions of exposure, in terms of the chance, measured in the same way, during a quiet period following an epidemic.

From Fig. 1 it will be seen that, instead of remaining level or only rising with extreme slowness up to the moment when an epidemic is about to begin, as I find occurs in other infectious diseases, the index steadily rises during the whole of the non-epidemic year, culminating in a sudden additional increase at the start of the epidemic and then a rapid fall during the epidemic. The gradual rise has evidently no relation to season, and must represent an immunity change. This index being a product of what I have called the *index of communal susceptibility* (or relative proportion of the children under 10 in the

FIG. 2.

Proportions no longer at risk

A (4) } Amongst susceptible children in same house as a case.
B (5) } In whole susceptible population.

paper went to press, I omitted to notice this interesting suggestion on page 18,

"in spite of the fact that in March the tenements still contained 49 children who had not had measles, only one further case of measles occurred. This fact may have been related to the chance of exposure. On the other hand, it suggests the possibility that during the progress of the main outbreak the presumably susceptible children who did not develop measles were exposed at intervals to small doses of the virus, and thus developed a degree of immunity. . . . In these circumstances, however, such an immunity would be temporary and partial, as the vast majority of individuals are destined sooner or later to undergo an attack of the disease. . . ."

Apparent Infectiousness.

Here we had a suggestion of that *temporary* latent immunisation in measles for which I produced some statistical evidence, to be further amplified in the present communication. Briefly, the evidence for this so far obtained depends upon (a) the behaviour of the index of apparent infectiousness between epidemics, and (b) a study of the subsequent behaviour of children who were contacts to a case of measles in their homes as compared with that of control groups. The *index of apparent infectiousness* for measles is defined in this way. If n cases of measles occur in any period of time t , and s children under 10 develop the rash in the same house as, and after an interval of 10, 11, 12, or 13 days from the appearance of the rash in, one of the n cases, then the apparent infec-

population who remain susceptible at the middle of the period), on the one hand, and the *index of true infectiousness* (or relative danger for a susceptible child of catching the disease if exposed to a case under standard conditions during the period), I have shown by the dotted line and shaded portions what are probably the relative parts played by these two factors. The hypothetical curve of communal susceptibility is derived from the changes which occurred in the population of susceptible children under 10 on the assumption of a latent immunisation of about four children to each clinical case and a subsequent loss of that immunity at a rate, suggested by other evidence, which would cause it to disappear in about two and a half years. The portions of the index above the dotted curve are in that case attributable to increased facility of transmission of the virus from person to person, and this at first sight appears to remain enhanced throughout the epidemic, but, as I shall show presently, this is only because we are dealing with a large area and looking at a composite picture for the whole of St. Pancras, for when analysis into small areas of a quarter of a square mile is made, it is found that as the epidemic successively invades these squares the index rises violently in each, and then subsides to a low level within about six weeks. . . .

In my original paper I was puzzled by the absence of any rise in the index during what appeared to be a small epidemic in 1925, and after pointing out

that the age distribution of cases in this outbreak was different from that of the two major epidemics, I stated on p. 305, "during two minor outbreaks in pre-epidemic periods the apparent infectiousness was temporarily greatly enhanced, but in another extra epidemic which chiefly attacked older children this was not the case." Not having touched the notification data of German measles when I wrote that, I failed to perceive that this extra epidemic almost certainly consisted partly, perhaps entirely, of German measles cases wrongly diagnosed, for a large epidemic of that disease was occurring at that time, the next being in 1929. This little epidemic of measles notifications seemed to constitute an exception to the rule that the index of apparent infectiousness must rise for an epidemic to occur, but it now appears that it is just the exception which proves the rule. It will be seen from Table II, that the definition of 10-13 days inclusive as the most suitable interval between cases for calculating the index for measles brings in about one-half of all possible intervals, whereas in German measles it would only bring in about one-fourth owing to greater variability of the incubation period, a fraction which would be further reduced on account of the higher age-incidence of German measles, and it therefore follows that any considerable admixture with cases of German measles must have the effect of depressing the index of infectiousness as defined for measles. When the German measles notifications are studied independently it is found that there was in fact a pronounced rise of infectiousness in this epidemic as in others.

After-history of Contacts.

In Fig. 3 is shown in diagrammatic fashion some of the evidence for temporary immunisation obtained by following up contacts through the 1926 epidemic and this indicates that at all ages up to 10 years children who were intimately exposed to infection but escaped immediate attack were after three months subject to about one-eighth of the attack-rate of a control group, but after 18 months had elapsed they were subject to nearly half that of the control group. The relative values of these fractions suggested a disappearance of latent immunity at such a rate as to be complete after about two and a half years. I have recently sought for further confirmation of this finding by taking out from the records of contacts 304 children aged 1-9 who had never had measles up to the end of 1927 and who had been exposed to infection from a case in the same house during the period March,

same extent as for the contacts, so we cannot measure the rate of decline from the size of this ratio alone, but as far as it goes it confirms the conclusions previously drawn.

Process of Immunisation.

In Fig. 4 an attempt has been made to show graphically what would happen to two groups of 1000 children each, (A) born simultaneously at the start

Evidence for latent immunisation in measles. Attack-rate during period C in children under ten who had never had measles but had been exposed to infection from a case in the same house during period A, in terms of expected attack-rate during the same period C.

of an epidemic, and (B) born simultaneously at the end of an epidemic, on the following assumptions: (1) that an epidemic recurred every two years, three-quarters of all cases in the two years occurring in the epidemic six months and one-quarter in the remaining 18 months; (2) that children fell victims to measles in successive two-year periods at the smoothed rates for each age obtained by Collins in his recent analysis of measles histories; (3) that latent immunes were produced at the rate of three to each case; and (4) that this latent immunity was lost at the uniform rate of 50 per cent. in one year and 100 per cent. in two years. The lower curves in the left-hand portion of the figure show the increase

TABLE II.—Distribution of Intervals between Pairs of Cases in the Same House in St. Pancras, 1924-28.

1926, to July, 1927, and following them through the epidemic of 1928. By correcting their ages to the beginning of 1928, allowing for removals in the interval as estimated from changes in the electoral registers and applying the case rates per 1000 children at risk in St. Pancras at each age, the expected attacks during each month of the 1928 epidemic were calculated and compared with the actual attacks. The numbers were not large enough for any detailed analysis, but for the whole group with a mean interval of 19 months between previous exposure as a contact and exposure to risk in the epidemic the actual cases were 28, giving an attack-rate per 100 of 9.21 ± 1.11 as compared with an expected rate of 14.50. There is a significant difference here and the ratio of actual to expected attacks was 0.63 after 19 months. It must be remembered that the expected attack-rate would also be reduced by residual latent immunity in the population as a whole, though not to the

in communal immunity due to attack, which would not proceed along a uniform curve but in a wavy manner. The upper curves, showing total immunity permanent and latent, indicate that by the end of the fourth year of life practically all the children would be rendered immune by an epidemic, of whom 10 to 20 per cent. would lose their immunity again before the next occurred. The oscillations due to gain and loss of immunity get smaller and smaller, and by the fifteenth year it must be assumed that about 10 per cent. have either passed out of reach of measles infection, acquired a fairly permanent immunity by repeated inoculation, or have had some immunity since birth of a permanent character.

If we now suppose the children born uniformly over the two years instead of instantaneously at two points, we obtain the distributions in the right hand portions of Fig. 4, which show the changes which occur on this basis in the permanent and latent

were so different in Chalk Farm (H 15) and Tufnell Park (F 16) that the epidemic started 12 weeks later in the one than the other. The sudden increase in apparent infectiousness must, I think, take place when the activity of the virus, certainly aided to some extent by seasonal influences, rises to a level P, and the latent immunity of the mobile portion of the young children in the area has sunk to a level L, such that the balance between P, L, the density of population D, and the amount of circulation in schools and streets C, swings past a critical point in favour of the virus.

It is just as though we kept on day after day inoculating a bacterium into a liquid culture medium to which some essential constituent, x , lacking to start with, is also being daily added in successive small quantities. No growth at all will occur until a critical concentration of x has been reached, and then rapid growth will suddenly commence. This, I think, is the best explanation of the sudden rise of true infectiousness which precedes the onset of an epidemic in most diseases I have studied, and in saying this I admit it is nothing but Gill's "quantum" theory stated in such a way as to make it rather easier to visualise. The culture medium for an epidemic is the non-immune human population, and free multiplication of the virus is only possible when

density or circulation or immunity level of the population may delay or prevent its further advance, in which case that area may escape until later when the infection pressure coming from some other direction is greater or the immunity level has fallen lower so that the balance is then upset—or it may escape altogether, owing to the season having advanced too far, until the next year or the next epidemic. This, I think, is the mechanism of spread of a measles epidemic through an urban community and it fits in well with some interesting observations made by Halliday in the discussion following a brilliant mathematical exposition of the Glasgow measles curve by Soper* to the Royal Statistical Society in December, 1928. He said,

"Now, measles as outbreak takes time to move through a community. In Glasgow, when an outbreak began in September, it was found that it took 24 weeks to pass over the 37 sections or wards of the city. On the other hand, if measles did not begin in the form of outbreak until January, February or March, it followed that the whole city would not be covered until June, July or August. But this did not happen because, owing to the interposition of another factor, the progression of the outbreak in space was frustrated in May or June."

This other factor was seasonal, and it followed, he showed, that an epidemic which started late in

FIG. 5.

A measles epidemic in space and time (St. Pancras, 1926): case-incidence and indices of apparent infectiousness in half-mile squares.

the "concentrations" produced by the factors L, C, and D reach a favourable level, and if this happens at a time when seasonal conditions are also favourable, multiplication is suddenly stimulated and facility of transmission increased. Once the balance is upset in this way the epidemic goes forward in the immediate neighbourhood, which means for a large area just behind the advancing edge of the wave, until practically all the children aged 3 and upwards are rendered temporarily or permanently immune, leaving unprotected only a proportion of very young children who have been sheltered by circumstances from infection. The wave thus spreads outwards until it reaches an area where changes in

a large city might leave large tracts of the city untouched and another epidemic might therefore follow in the next year, whereas in smaller towns such as Greenock and Dundee this would not occur, and a regular biennial periodicity was there the rule.

This problem has, of course, been studied some 12 years ago by Brownlee,⁹ and it has been suggested that I dismissed his conclusions in somewhat cavalier fashion in my original paper,¹⁰ but my reason for only making brief reference therein to his well-known work was that, whilst I saw that the interesting facts he brought to light by periodogram analysis—for example, that there were distinct periods of 97 and 87 days observable in the recurrence of measles

epidemics in different parts of London, might have an entirely different explanation than the one he gave for them (biological cycles of development of distinct strains of the virus), I had then no data which would enable me to make more than a speculative suggestion about this. I think, however, that the method used in Fig. 5 may enable us to settle this question when we have been able to make a similar analysis of several successive epidemics in the same area, and in the meantime I will only point out that the facts already brought out in Fig. 5 alone—for example, the mere fact that the sudden rise in infectiousness which was the starting point of the epidemic occurred 12 weeks later in square H 15 than in F 16, seem to make it most difficult to accept the explanation Brownlee gave. At the same time they supply grounds for believing that a more interesting reason than the one he propounded will be found for the phenomena which his work brought to light.

Conclusion.

In conclusion we may ask, how does this help us to prevent epidemics of measles? Let us glance one by one at the factors which seem to be involved in the upset of balance which starts the epidemic. The activity of the virus P is beyond our control, and so is the march of the seasons, and the density of population D is a matter which can only be slightly and gradually improved. The circulation C, by which is implied the amount of contact between young children, has been shown by Halliday's researches on the conditions in Glasgow tenements to be of great importance, and here improved housing and, most important in my view, independent access to dwellings rather than common staircases wherever possible, can accomplish much. Careful supervision of nursery schools and infant classes by school nurses during epidemic periods, such as is being practised in some areas of London, should also do something to reduce the exposure to infection of very young children to a minimum. But it must be admitted that the only hope of really preventing these epidemics altogether is through the immunity factor I, for if we could maintain the level of communal immunity at a sufficient height to prevent the balance being upset no epidemics need occur. To do this it might be necessary to ensure that three-quarters of the whole population were temporarily or permanently immune, and unless a method of artificially producing a fairly permanent immunity is found, this would soon become impracticable, for as children grew up under such protection more and more adults would be at risk and liable to attack. It seems, therefore, that as a matter of practical politics we must hope for either a simple method of inoculation which will produce a more or less permanent immunity, or else a simple method of rendering an attack abortive and harmless, such as the proposed method of inoculating contacts with their parents' blood, whilst at the same time allowing it to produce a permanent immunity. From many points of view the latter seems the most promising line, for, even if a certain method of permanent protection were discovered, experience with small-pox vaccination makes it doubtful whether the necessary proportion of the population would accept such protection. It may well be that further knowledge of the march of events which take place as the epidemic wave front approaches a district may enable us, without ever having isolated the virus, to so choose our time in applying some simple method of partial and temporary protection as to allow the wave to immunise most of the children for us without the distressing features, mortality, and after-effects, which we now have to associate with a measles epidemic.

Towards the accomplishment of this end there is only one way—more research from both aspects, experimental and statistical.

Clinical and Laboratory Notes.

IMMUNISATION OF A FEVER HOSPITAL STAFF AGAINST DIPHTHERIA.

By E. H. R. HARRIES, M.D. LOND., D.P.H.,

MEDICAL SUPERINTENDENT, BIRMINGHAM CITY INFECTIOUS DISEASES HOSPITALS.

THE Birmingham City Hospital, Little Bromwich, was amongst the earliest of the large fever hospitals to introduce the Schick test and the active immunisation of the positive reactors amongst the staff. The results in the earliest years have been submitted to statistical analysis by Hilda M. Woods,¹ who showed that whereas during the three years immediately preceding the introduction of immunisation the attack-rate was 17.8 amongst an average nursing staff of 90, the rate during the years 1922-24 was 3.7 per annum amongst an average nursing staff of 108. Woods showed that the difference between the attack-rates for the two periods was more than four times the probable error—"a greater difference than would be expected as the result of chance alone."

The purpose of this note is to record the results from 1922 up to the end of 1929. Schick testing of

* Reconstruction of some scarlet fever wards.

- (a) Differentiation of nursing staff by Schick test commenced Jan. 28th.
- (b) Active immunisation of nurse-positive reactors commenced in last quarter of year.
- (c) Active immunisation of nurse-positive reactors through year.
- (d) Schick testing and immunisation of domestic staff also, from 1925 onwards.

the nursing staff commenced in January, 1922. From then onwards only nurses who were Schick-negative reactors have been allowed to work in diphtheria wards; but it should be stated that active immunisation of the positive reactors was not commenced until the last quarter of 1923. Until the end of 1924 only the nursing staff was Schick tested and immunised. From the beginning of 1925 onwards a similar procedure was adopted for the domestic staff

also, since when no nurse or maid has been allowed to work in a diphtheria ward until known to be Schick negative, whether as the result of active immunisation or not. No Schick-negative reactor has contracted clinical diphtheria. The above Table sets out the main facts. The average yearly strength of the nursing and domestic staffs is given.

It is clear that the average strength does not represent the real number of persons at risk in any year. Changes amongst the members of both staffs result in a varying number of fresh non-immunes being at risk for short periods in each year. For example, in 1929, there were 129 nursing and domestic new entrants of whom 41 (31.7 per cent.) were Schick-positive reactors. In the Table is also shown the crude number of cases admitted to the hospital with a diagnosis of diphtheria in each year. This figure includes all cases of so-called bacteriological diphtheria and all cases in which the diagnosis was revised to some other condition. The number of cases of true clinical diphtheria admitted in each year was from 21 per cent. to 33 per cent. (1929) less than these crude totals.

The immunising mixture first used was toxin-antitoxin (T.A.T.), later toxoid-antitoxin (T.A.M.), or modified toxin (M.T.), and during part of 1928 and throughout 1929 toxoid-antitoxin floccules (T.A.F.). So far as our experience has gone with the last-named preparation, it would appear to be superior in immunising value to any of its forerunners—i.e., in rapidity of immunisation. Its use in the immunisation of adults has been attended by a notable freedom from reactions.

THE FETAL HEART BEAT.

AN OBSTETRICAL EXPERIMENT.

By C. RUSSELL CORFIELD, M.D. BRUX., L.M.S.S.A., D.T.M.,

CHIEF MEDICAL OFFICER, HIGHTFIELD HOSPITAL, SUNDERLAND;
LATE OBSTETRIC HOUSE SURGEON, ST. MARY'S HOSPITAL,
MANCHESTER.

AN interesting experiment has recently been concluded in the obstetric department of this hospital, the object of the research being: (1) to verify the statement that the maximum point of audibility of the foetal heart beat is a reliable guide to the ultimate presentation; (2) to determine, if possible, the relationship of the rate of the foetal heart beat to the sex of the child; and (3) to determine the possibility of a relationship between the age of the mother and the sex of future children.

Three separate groups of a hundred cases each were included in the experiment, and with few exceptions the findings were almost identical in each group.

It was found that the foetal heart beat in quite normal cases has a wide range, much wider than 130 to 150 with an average of 132, as taught in many text-books; therefore an apparently unduly slow or rapid rate does not necessarily foretell distress or disaster to the child. The average rate lay between 112 and 180 per minute, and on further investigation these rates fell into six distinct and well-marked groups, each with an average age-incidence and sex value.

Group.	Average foetal heart beat.	Average age-incidence.	Percentage of predominant sex.
1	112 to 120	27.6	66.6 females.
2	121 to 130	28.16	58.3
3	131 to 140	24.74	51.1 males.
4	141 to 150	28.0	57.1 females.
5	151 to 160	28.85	75.0
6	161 to 180	35.0	100.0 "

This Table suggests that a woman's chance of bearing a son is 2 to 1 against if she falls into groups 1 or 2; this is against the usual teaching that suggests that a low pulse-rate favours the male.

The majority of births fell under group 3 with a foetal heart beat of 131 to 140, an age-incidence of 24.74, and a sex value of 51.1 in favour of the males. It will be noted that this is the only group where the males predominate. In group 6 were placed the later primiparae and multiparae; here we find the highest age, foetal heart beat, and female sex value 100 per cent.

The following suggestions are gleaned from the results of this small research.

(1) There is no doubt that the position of the maximum audibility of the foetal heart is a fairly reliable guide to the ultimate presentation of the child; no less than 75 per cent. were found to be correct.

(2) It cannot be said that the foetal heart beat foretells definitely the sex of the foetus, but there certainly appears to be a relationship and a fairly well-established range of foetal heart beats at different ages. The fact that in groups 1, 2, 4, 5, and 6 the predominant sex is female suggests that a foetal heart beat of 141 to 180 in late primiparae and multiparae favours the prognosis of a female child.

(3) There is no doubt that the chances of a woman having male issue become less as she travels along the child-bearing period. This might be an interesting point in medico-legal argument, and in questions as to the desirability of late marriage.

(4) The experiment suggests that the best age of expectation for male issue is between 24 and 25 years of age.

New Inventions.

A LARYNGEAL MUCUS EXTRACTOR.

I HAVE devised a simple piece of apparatus by which mucus can be extracted by suction from the mouth of the infant without any risk of its reaching the mouth of the operator. A thorough trial has been given to this pattern in the Rotunda Hospital Dublin. It comprises two portions of metal tubing connected by an intermediate chamber, itself divided

into two parts, which can readily be separated for cleaning. Within the upper portion or lid of the chamber is a detachable baffle in the form of a conical disc or dome provided with a U-tube, one end of which passes through the centre of the dome and screws into the suction tube, whilst the other end terminates on the upper surface of the dome which dips into an annular recess in the lower portion of the chamber. The trap thus provided prevents any mucus reaching the chamber from passing up the suction tube.

The instrument is made by Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, London, W.

AMIN BUKTOR RUFAL, M.R.C.S. Eng., L.R.C.P. Egypt.

NOTTINGHAM HOSPITALS.—Nottingham General Hospital last year admitted 8755 in-patients who cost £2 10s. 9d. each per week, a slight reduction on the previous year; the average cost per occupied bed was £155 8s. 9½d. The Hospital Saturday Fund raised over £30,000.—Almost the final act of the Nottingham Board of Guardians was to open recently a new Children's Hospital at Bathgate, which has cost £40,000. Accommodation is provided for 56 children under 8 years of age, and an equal number of older ones; another block provides for 42 convalescent children, and there are two isolation wards.—It has been decided to enlarge the Nottingham and Notts Convalescent Homes at Skegness by erecting a new Home for Women at a cost of £15,000. Last year the Homes received 1461 patients.

Medical Societies.

TUBERCULOSIS ASSOCIATION.

ANNUAL CONFERENCE AT OXFORD, APRIL 3RD TO 5TH.

MEMBERS enjoyed the hospitality of Somerville College and the meetings were held in the Pathological Theatre, the chairman being Sir STCLAIR THOMSON, President of the Association.

CONTACTS.

The discussion was opened by Dr. G. JESSEL (Cons. Tub. Officer, Lancs C.C.). The examination of contacts was, he said, not regarded by most tuberculosis officers with any degree of enthusiasm, it being generally felt that the results of contact examination were not commensurate with the labour and time involved. As there appeared to be no available statistics proving or disproving this point, he had recently undertaken an investigation in his area in Lancashire, comprising a population of over 300,000, with the object of discovering how many secondary cases of pulmonary tuberculosis occurred up to the end of 1929 which could be related to cases investigated and accepted as tuberculous by the tuberculosis officers during the years 1921-24 inclusive. Thus in this period there was a minimum period of five and a maximum of nine years for the possible discovery of the secondary or contact case. The results showed that in 15 per cent. of the primary cases accepted as pulmonary tuberculosis there were instances of one or more secondary cases of tuberculosis following. Nearly all these secondary cases were directly related to primary cases which had tubercle bacilli in their sputum, whilst the average interval between the discovery of the primary and secondary cases was three and a half years. There was thus a statistical basis for believing that contact examination at or about the time of the diagnosis of the primary case was usually barren of results, though, of course, there were exceptions, especially in young adults. A house contact had been defined as a person who had lived in the same house with a known tuberculous patient within six months of the date of examination of the contact. The investigation he had quoted showed that this period was much too short. He thought a minimum of four years was desirable, though there were serious practical difficulties in the way of lengthening the period.

Dr. Jessel then went on to quote figures for Lancashire for the four years 1925-28, extracted from the annual reports of the central tuberculosis officer. For the most part the contacts examined were, in reality, suspects, and the figures showed a rate of 74.8 tuberculous per 1000 contacts as compared with a rate of 4.83 tuberculous per 1000 general population. The percentage of tuberculous contacts which had tubercle bacilli in their sputum was 31.7. He also outlined his method of contact examination and emphasised the following points: (1) it was not difficult to pile up large figures by examining all and sundry, and (2) persons in good health readily submitted to examination, and reluctance to be examined was often a suspicious feature of a case.

Although many tuberculosis officers preferred to examine contacts at the dispensary, Dr. Jessel thought there was much to be gained by examination at home. In the past too much attention had been paid to the child contacts and too little to the adults. In conclusion, he believed that the most profitable contact examination work was to be done amongst the families in which a sputum-positive case had occurred. Even here it was most profitable to limit one's energies to genuine suspects. A single negative examination might well lead to a false sense of security, and, if possible, re-examinations should be

made at intervals for at least four years. Home examinations should not be neglected and attention should be paid to adults, especially middle-aged contacts. Workroom and office infection should receive also more attention; here welfare workers might help. Dissemination of knowledge in health subjects was important, as were energy, enthusiasm, and tact in overcoming difficulties.

Dr. NOEL BARDSWELL (Princ. Asst. Med. Officer, L.C.C.), on the principle that the tuberculosis officer saw most of the game, stated that he had issued a questionnaire to the 30 tuberculosis officers of the London boroughs. The questions and answers he summarised as follows: (1) What steps do you take to ensure the examination of contacts?—The answers stated that with the exception of one borough where a special session was set apart for contacts, the matter of getting up the contacts was largely in the hands of the health visitors. (2) Do you experience much difficulty in securing attendance of contacts?—The answers indicated that there was difficulty especially with the young adults and those who were ailing and did not wish their worst fears to be confirmed. One tuberculosis officer reported that contacts from better-class districts were more willing to attend than were those from poorer districts. (3) What proportion of contacts attending were diagnosed positive on (a) first attendance, and (b) subsequent visit?—Taking all the figures together the positives were 8.2 per cent., the figure for the whole of England and Wales being 12.7. For children only the positives were 2 per cent., as compared with 6.3 for England and Wales. Figures for the different boroughs showed considerable variation in the number of contacts who were found to have a positive sputum. (4) What proportion of contacts lapsed before a diagnosis was made?—The answer was "very few." (5) To what extent are negative contacts followed up?—The responsibility of keeping in touch with the contact as long as the focus of infection remained was mainly left to the health visitor. (6) Of what value was the school medical service in giving oversight to suspected children?—There were numerous advantages: (a) continual supervision, (b) provision of country holidays, (c) early reference of cases to the tuberculosis officer, (d) facilities for treatment of intercurrent illnesses. In conclusion, Dr. Bardswell said that the tuberculosis officers appeared not to be entirely satisfied with contact examination. How far the records of these examinations bore upon the whole question of infectivity he was not prepared to say. If tuberculosis was ubiquitous the important question still remained: Why does it declare itself only in some people?

Dr. W. BURTON WOOD (Cons. Tub. Officer, Essex C.C.) said that nobody would deny the importance of the examination of contacts, but warned his listeners against the danger of catch phrases, half-truths, and the type of administrative control which might confuse the issue. He drew a vivid picture of the harassed mother trying to do her best and bringing her younger children up for examination, but failing to exert pressure on the adolescent son and daughter who were the most likely members of the family to be positive. Statistics were satisfied and the mother greatly relieved because her young children were pronounced healthy, whilst the chief danger was overlooked. For the task in hand adequate time was needed, together with proper clinical assistance without which clinical acumen was smothered in foolscap sheets whose abbreviated designations absorbed the whole alphabet. Sufficient radiograms were also needed but they should be of good quality and not resemble a myope's vision of a November fog. Expense was wholly unjustified unless it yielded an adequate return. In all well-conducted inquiries into contacts there should be three questions: By whom was the patient infected, whom has he infected, whom may he infect? The first question was often insoluble. Even the harmless necessary cow, despite Mrs. Turner's cautionary tale that "cows do no harm," might be to blame. The

examination of child contacts needed the imagination of a poet, the ear of a piano tuner, and the touch of an osteopath, and there were still clinicians who regarded a child's chest as a kind of Abrams box. Without minimising the importance of the fact that occasionally among child contacts a positive case might be found calling for the closest scrutiny, he thought the statistics of children examined and found negative had no value. He stressed the importance of the young adolescent contact, often beginning with a broncho-pneumonic patch in the subclavicular area and rapidly progressing—the true early case of the infected house. All dispensary arrangements as to contacts should be made subservient to the convenience of this type of patient. Influenza, febrile colds, lassitude, slight blood-spitting should be the signal for immediate and searching examination with X ray control, for X rays had proved how slender was the connexion between physical signs and pathology. In his experience it was very rare to find an early adolescent consumptive who had previously belonged to the swarm of children who buzzed like flies round the dispensary malt-and-oil pots. He found it difficult to believe that mere observation, however prolonged and benevolent, could suffice to prevent consumption. We knew little about primary infection and still less about its relationship to frank disease, but we could, by using every modern aid, diagnose pulmonary tuberculosis in its early infiltrative and exudative stages when treatment could be employed with a hope of success.

Discussion.

The CHAIRMAN said he was impressed by the large number of infected contacts, the importance of the radiogram, the number of unknown factors in infectivity, and the value of actuarial control of the statistics.

Dr. G. MACDONALD (Battersea) found that 60-70 per cent. of contacts were uninfected children. A definite standard of positive diagnosis of childhood tuberculosis was needed. At present too much was left to the personal factor of the physician.

Dr. F. J. C. BLACKMORE (Woolwich) thought more figures were required before any useful conclusions could be arrived at.

Dr. MIDGLEY TURNER (Worcestershire) pleaded for a broad view of the contact. He visualised three zones—viz., house contacts, infected factory contacts, casual contacts. In the first zone he had found 101 fatal cases yielded 833 contacts with 11.6 per cent. positive cases.

Dr. J. CROCKET (Glasgow) found 23 per cent. of his patients had a history of contact.

Dr. C. H. C. TOUSSAINT'S (Bermondsey) figure was 16 per cent. He also gave figures showing that in a collection of cases of tuberculous meningitis nearly half proved to have had a tuberculous parent.

Dr. D. J. WILLIAMSON (Ministry of Health) thought that the value of contact examination depended upon the care exercised in selection. Figures given showed that the contact population had a higher percentage of positives than had the general population. Contact examination was valuable also as a routine examination of a section of the whole community.

Dr. E. WARD (Devon) emphasised the value of contact examination in the home as against dispensary examination, and stressed the help of the general practitioner.

Dr. L. S. T. BURRELL (Brompton Hospital) said the older he got the less inclined he felt to place faith in mere physical signs. The gland case in childhood did not become the adult phthisic. The adolescent case was all-important.

Dr. P. ELLMAN (East Ham) said the old age cases were a great source of trouble, they disliked examination, and were careless and unhygienic.

Dr. W. TEMPLETON (West Sussex) laid stress on the risks of engaged couples amongst the young adult cases.

OLEOTHORAX.

Dr. GILBERT (Leysin) gave his seven years' experience of oleothorax, which method of treatment he considered to be a good adjunct to artificial pneumothorax when used with judgment. With regard to the mode of action of oil injected into the pleural cavity, he considered that at least four practical results were obtainable: (1) disinfectant action in febrile and bacilliferous pleural effusions; (2) the rendering of the pleural layers thick and impermeable; (3) collapse and compression of the lung; (4) the thickening and making rigid of a healthy pleura, thus impeding the displacement of the mediastinum. The therapeutic indications for oleothorax were the treatment of: (1) certain types of pleurisy complicating artificial pneumothorax (especially serofibrinous and puriform effusions which had become chronic, and true purulent effusions); (2) pleuro-pulmonary perforation (e.g., emergency oleothorax for overcoming immediate distress, or for complications when fistulous opening was small); (3) unsuccessful artificial pneumothorax due to insufficient compression (though there were sometimes contraindications when a partial pneumothorax only had been obtained); (4) progressive emphysema pleuræ which was interfering with successful collapse; (5) mediastinal laxity; (6) as an eventual substitute for air when it was essential to avoid frequent refills. The accidents and complications met with were febrile reactions, perforation of lung, too high intrapleural pressure owing to increased secretion of pleural fluid. Dr. Gilbert described two methods of administering the oil: the one, direct, with a 20 c.cm. syringe; the other with a bulb, such as is used for storing antitoxic serum, with a needle attached to one end and a small bellows apparatus to the other, the antitoxin bulb containing the oil being surrounded with a suitable warm-water jacket. The oils used were liquid paraffin and olive oil, the latter with 5 per cent. oil of gomenol added being the best. The oil must be absolutely pure, it must be sterilised before use, and administered warm. Quantities up to 500 c.cm. could be injected according to circumstances and it was advisable to leave above the oil a small area of negative gas pressure, though a complete "blockage oleothorax" was sometimes carried out. When used for fluid replacement the fluid should be evacuated before the oleothorax was attempted.

In conclusion Dr. Gilbert showed an illuminating set of lantern slides.

Discussion.

Mr. H. MORRISTON DAVIES (Ruthin) spoke of the value of oleothorax in the treatment of pyopneumothorax. An intolerant pleura could often be made to acquire tolerance. Oleothorax was often valuable in eliminating the necessity for constant refills.—Dr. H. DE C. WOODCOCK (Leeds) gave his experience of 300 oleothorax operations. It was a cardinal rule never to do an oleothorax before an artificial pneumothorax. He had used the method as a treatment for interlobar and encysted empyemata. He had found it useless, however, for controlling hæmoptysis.—Dr. PETER EDWARDS (Nantwich) raised the question of the difficulty of checking the intrapleural pressure and was puzzled by the divergent views as to the antiseptic powers of gomenol.—Dr. CROCKET emphasised the risk of shock and febrile reactions, and stated that he had found a Woodcock manometer useful for recording pressure.—Dr. E. T. D. FLETCHER then recorded an interesting case.—Dr. NIVEN ROBERTSON suggested the possibility of combining oleothorax with phrenic avulsion.—Dr. S. R. GLOVNE (Victoria Park) gave his experience in performing oleothorax on rabbits.—Dr. SEDMONDS spoke on the absorption of fluid in oleothorax, and Dr. BURTON WOOD raised again the question of difficulties of controlling intrapleural pressure.

TUBERCULOSIS COLONIES.

Dr. J. B. McDUGALL (Preston Hall) said that two charges in particular had been lodged against village settlements—viz., that they were expensive and that

they catered only for the few. It was his personal opinion that the delay in the development of village settlements generally had been due to the fact that settlements were assumed to be necessarily expensive and therefore, as far as authorities were concerned, prohibitive. In studying the finance of village settlements conducted on the lines of the Papworth and Preston Hall schemes it was essential to divide the account into three distinct sections—viz., sanatorium, estate, and industries. The subject had then to be considered from the standpoints of capital expenditure and maintenance. In analysing the various returns from settlements he had found it difficult to make comparisons in capital expenditure between one settlement and another because of the different systems employed in presenting the accounts. At Preston Hall the most suitable division of the estimated initial capital expenditure was as follows: Sanatorium section £19,300, estate section £18,070, industries section £1000, to which a further capital sum of £13,654 had been added in the sanatorium section since 1925. On the sanatorium section account, therefore, the total capital expenditure, including the initial valuation, could be put at £32,954, which was approximately £178 per bed, a figure which compared very favourably indeed with other institutions. This relatively low figure was due to the large number of patients housed in hostels and huts. The estimated expenditure on estate section was £48,856. For this sum the Legion could show 121 houses, all, with two exceptions, occupied by ex-patients with their wives and families. The relatively low cost of £403 per house was due to the smallness of the original valuation. These houses, built by capital raised by voluntary subscription, assisted the housing problem of public authorities. Thus, one council had, at present, no less than 27 ex-patients in residence at Preston Hall as settlers and the indirect saving to that particular council was considerable—a point which the critics did not always appreciate. On the remainder of the estate at Preston Hall there had been no capital expenditure beyond £1270 estimated in the original valuation. There was a valuable hidden asset there. When the British Legion assumed control the only department in the industries section which was kept on was the appliance department, the value of which was well covered by £1000. Since 1925 £16,544 had been spent in providing workshops and machinery, bringing the cost of the industries section up to £17,544. They had 145 settlers at Preston Hall, of which 135 were working in three departments of these industries. Dr. McDougall was of opinion that this number could be increased to 140 without additional capital expenditure. The capital expenditure, therefore, to enable each man to become permanently a more or less economic unit was approximately £125—i.e., less than the cost of the treatment of one patient for one year in the majority of sanatoriums in this country—an estimate which he believed would apply to other colonies.

It had been the practice at Preston Hall, Dr. McDougall said, to deal with maintenance under three heads also—sanatorium, estate, and industries. The sanatorium section was obviously in the hands of local authorities who had patients to send them, and the ex-Service men were a diminishing quantity. With these difficulties and a fluctuating bed list there were necessarily fluctuations in the sanatorium balance-sheet. During the past year, however, they had been able to administer the unit and preserve financial balance by charging local authorities £2 12s. 6d. per patient per week. In 1927-28 there was a profit of £105, in 1928-29 £195. In the estates section the incomes came from rents. Villagers paid from 4s. to 9s. per week and no rates. Neighbouring farmers rented portions of land. On the expenditure side there were the wages of the settlers on the estate staff, audit charges, &c. No allocation for depreciation had yet been made because the initial valuation of the estate property had been on the conservative side. Probably a reserve fund would ultimately be

set up to meet this depreciation. Owing to the growth of the neighbouring town of Maidstone the capital value of the Preston Hall land was appreciating each year. The estate accounts for 1925-26 showed an excess of income over expenditure of £978. If economic rents had been charged the income would have been almost double.

The industries section showed total sales of £198,024 between 1925 and 1929. Salaries, wages, and commission during that period came to £66,160. No interest on capital was debited to the industries account and no portion of the medical director's salary was included. The average loss per annum during the period was £1080—i.e., a loss of 1.8 per cent. on a turnover of £198,024. The average number of settlers on the wage list during these years was 95 and the average loss per annum per settler was therefore £11 7s. 4d. The results of the present year had convinced him that it would be possible to run the industries at a loss of £10-£15 per settler per annum. The problem of orders and labour was baffling. It would be easy to go into the open labour market and engage hands to catch up with excess orders, but that policy would not stimulate the healthy growth of the settlement. The industries section was only one part of the settlement, and the British Legion had, at Preston Hall, regarded the three sections as one unit. In conclusion, there were many thousands of tuberculous patients receiving more per annum from approved societies and disablement benefit than was necessary as a subsidy to keep them at work as productive units in a settlement.

Dr. E. L. SANDILAND (Barrowmore Hall) emphasised the wastage in life and labour which went on daily by the present method of discharging a patient direct from a sanatorium on to the labour market or the ranks of the unemployed. The ideals of a tuberculosis settlement had been often stated, but could they be put into practice at a reasonable cost? The experiences of Papworth, Preston Hall, and Barrowmore Hall had shown that they could. The latter had come through a rickety youth unsupported by financial vitamins from the Government and now only required an annual premium of public support to ensure its future. It had now 120 sanatorium cases, 12 cottages, and a hostel for ten single settlers. Eight dependents had been employed in the settlement, though none as yet in the industries. Three advanced cases had died 18 months after settlement, being employed for short hours during that period, and five unmarried settlers had left, in some instances to get work elsewhere, in others to get married. There were now 26 settlers on the estate. A table was shown giving the length of time these men had been settled and their periods of invalidity. The industries carried out were woodwork, upholstery, boot repairing, decorating, poultry farming, gardening, and clerical work. Of these 26 settlers, 12 had had tubercle bacilli in their sputum. The amount of time lost through sickness was 2.2 per cent. of the working hours. There was a special fund from which the dependents could be assisted during these short periods of illness. Dr. Sandiland stated that experience had impressed upon him the following facts: (1) tuberculosis settlements have a definite place in any antituberculosis scheme; (2) one colony is sufficient for a large area, if adequately supported; (3) the sanatorium section must be the centre and controlling authority of the whole settlement; (4) all workers must be under continuous medical supervision; (5) the sanatorium section must be kept full in order to have a good supply of possible settlers from which to select; (6) the medical superintendent must have a personal interest in everybody in the settlement; (7) skilled labour is expensive to train, there must be industries which will absorb unskilled labour; (8) settlements should be made by extending existing sanatoriums; (9) they should be of size most suitable to function economically; (10) much depends upon the type of men chosen for the early settlers; (11) although there may be small beginnings

foresight is essential; (12) a study of suitable markets and trades is essential; (13) settlements should be near big centres of population; (14) the financial side must not be fettered by restrictions—a certain amount of floating capital is necessary; (15) a settlement, with its sanatorium, should aim at accepting all types of case.

Discussion.

Dr. BARDSWELL asked why no public authority had undertaken a settlement. One reason was that those authorities had never had the financial position clearly put before them. The finances of the scheme must include the failures as well as the successes, and a large pool of subsidised labour seemed to be necessary to reinforce the trained skilled settlers if success was to be attained. At present public authorities dare not consider schemes which benefited only a small percentage of the tuberculous population needing assistance.

Dr. A. SANDISON (Min. of Pens.) believed that the choosing of medical superintendent and settlers was a highly skilled occupation in itself. He was also impressed with the divergence in figures of losses at different settlements. One difficulty which he foresaw was the automatic blocking of the waiting-list which would naturally occur as time went on.

Dr. EDWARDS agreed that the capital cost of a settlement was too high for any public authority to face nowadays. He also believed that any profits made should be left in the scheme, which a public authority would not do. Patients capable of being reabsorbed into the ordinary life of the outside world should not become settlers.

TREATMENT BY TURTLE VACCINE.

Dr. W. C. FOWLER (Pinewood) said the vaccine consisted of a living culture of an acid-fast bacillus isolated from a sea turtle cultivated by a special method not divulged. It was put up in sealed capsules in three strengths—very weak, weak, and strong. It had to be used within one month of its despatch from the laboratory, and microscopic examination showed the presence of acid-fast bacilli with a marked tendency to clumping. No contaminations were found. The bacilli were only feebly acid-fast as compared with Koch's bacillus and were shorter and thicker. Advanced laryngeal tuberculosis, lupus vulgaris, and meningitis were excluded from treatment by its sponsors. One injection only was required—subcutaneously in the gluteal region—and as a rule no immediate reaction followed. From 14 days to five months later in more than half his cases a small dusky red subcutaneous nodule appeared. The nodule generally remained for several weeks, discharged a slightly turbid serum, and healed as a depressed reddish scar. Pain was present but not severe. He had observed no secondary infection. Of 22 more or less chronic stationary pulmonary cases four had definitely improved, three had slightly improved, one had died of hemoptysis, two had more slight hemoptyses, two had developed tuberculous enteritis, and the rest had shown no appreciable change. Of four advanced pulmonary cases two had died and one was very ill. Of ten artificial pneumothorax cases improvement had followed in seven. Of eight early cases two had done remarkably well, four were doing well, and two showed no progress. One case of tuberculous peritonitis with effusion had gone downhill, but after paracentesis had improved.

Dr. G. E. SOLTAU reported that a number of early cases had been treated at Nayland with, on the whole, satisfactory results.

Dr. A. H. LANKESTER reported 44 bone and joint cases treated at Carshalton. Of these, 19 cases proved to be definitely tuberculous; five had much improved after vaccine treatment, eight had slightly improved, three were in statu quo, and three were worse. The remaining 25 were cases in whom subsequent investigation negated the diagnosis of tuberculosis. They had all much improved.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY.

At a meeting of this Section held on April 2nd, Sir HOLBURN WARRING, the President, in the chair, a discussion on

AMPUTATIONS AND THEIR RELATION TO THE ARTIFICIAL LIMB

was opened by Mr. C. MAX PAGE. Though amputations were, he said, the oldest branch of surgery, teaching on the subject was largely academic until the Great War forced its practical aspects on the medical profession. The 50,000 amputees in this country had provided a stimulus to both surgeon and limb-maker. He was limiting his remarks to the technique and treatment of amputations in which sepsis was absent, or present only in a subsidiary form. The aims governing the technique of any final major amputation of either upper or lower extremity could be thus stated:—

1. That the stump should provide a lever of sufficient length and power for the attachment of an artificial limb suited to the level of the amputation.
2. That it should be covered closely by healthy, well-nourished skin or scar, both of which should be mobile on the deeper structures.
3. That no part of the stump should be tender on pressure, nor unduly sensitive.

Leg Amputations.

The first question to arise in a given case was what level of bone section would, under the circumstances, give the most useful stump. In the leg, amputations could be considered under the headings (a) the Syme, (b) the below-knee, (c) the above-knee type. The first was essentially an end-bearing stump, and still had popularity, both in practice and as what he might call an examination gambit. During the war the Syme was entirely condemned in septic cases, and it was important to decide how far it was of value in civil work. Those who had seen a number of these cases would agree in condemning it, as a large proportion did not bear the test of time and in any case could only be fitted with a clumsy prosthesis. He had himself seen a good many Syme's stumps giving good service; he had also been called upon to reamputate a number which were painful and of no functional value.

The below-knee amputation gave a most satisfactory stump if 6 or 7 inches of tibia could be left; indeed, control of the knee could be obtained with as little as 4 inches. If more than 7 inches of bone was left, the skin covering was not well nourished, and the stump was practically certain to ulcerate or be the seat of eczema. It was agreed among surgeons that the fibula should be cut 1 inch above the level of the tibial section. In the case of short stumps he thought it a good thing to take the fibula out altogether, as the head of it often caused awkward friction areas when an artificial limb was fitted.

For above-knee amputations, section of the femur 4 to 6 inches above the level of the knee-joint seemed to give the best functional results; amputations done through the knee-joint were clearly undesirable, but in America, Canada, and Germany the Stokes-Griffith was popular. At pensions hospitals the usual experience was that an end-bearing thigh stump gave trouble sooner or later, the ideal stump being one containing 10 to 12 inches of femur, to which an ischial bearing prosthesis was fitted. Amputations of the thigh at a higher level could often control in a satisfactory manner an artificial limb up to a length of 4 inches from the great trochanter. If less bone than this was available, it was better to resect the femur at its neck, leaving the head of the bone in the acetabulum. To this could be more conveniently fitted a tilting table prosthesis than when 2 or 3 inches of femur had been left in.

Arm Amputations.

The question of level could, said Mr. Page, be generalised much as in the lower extremity. The points in the technique in any amputation which seemed to give the best results could usefully be considered in relation to flap-cutting, the bone section, and nerve-end treatment. In this country it seemed to be generally agreed that the end of the bone in an amputation stump should be covered only by skin. Flaps should be so cut that their nutrition and their innervation were as far as possible preserved, and therefore some muscle and fascia should be included in the base of the flap. Clearly, the shorter the flaps the better their nutrition, and in general the skin could be cut as in a circular or elliptical amputation, such short side-cuts being made as were necessary. Long flaps should be avoided. The scar which united the flaps should come on the posterior aspect of the stump in the case of the leg, while in the upper extremity it should be approximately central or terminal. The total length of the flaps designed should not much exceed the diameter of the limb at the level of the bone section. Redundant loose covering of the stump, especially in fat persons, interfered with the successful fitting of a prosthesis.

In cutting through the bone the aim was to prevent spur formation, yet it must be admitted that many stumps showing it were satisfactory. He thought spur formation was due to a tearing up of the periosteum at the time of section, or to the extrusion of marrow containing bone-forming cells. This could be prevented by dividing periosteum half an inch above the proposed line of bone section, and scraping it down the shaft. In that way the saw-cut was made through bone which was denuded of periosteum. Attempts to cover the cut end of the bone with an autogenous or pedicled graft were not much favoured in this country.

Treatment of Cut Nerves.—Drainage.

So far no procedure had given certain promise of preventing the formation of an end-bulb. The nerves which subsequently gave most trouble were those which arose in the smaller cutaneous branches. The stump of the nerve should not be attached to the scar, nor should it lie where it could be pressed on by the prosthesis. He did not think it was satisfactory in practice to pull down the larger nerves and cut them high up; he had seen severe post-operative pain which seemed to have been attributable to the trauma of the nerve trunk. He preferred to crush and cut all recognisable nerves about an inch away from the level of the bone section, following this by the injection of absolute alcohol into its stump. It was important to secure freedom from pain following the operation, the time when the nervous system was most sensitive. Otherwise there might ensue a jactitating stump.

As a general practice he thought it well to carry out drainage for 24 to 48 hours. Hæmatoma in early stages was most undesirable; not only did it interfere with the skin nutrition, it was liable to be followed by a low-grade suppuration.

Finally the views he had enunciated he wished to be regarded as applicable to stumps which were expected to be final in character. The full function of a stump depended on its normal position being maintained during convalescence, and keeping its musculature in good condition. The importance of avoiding post-operative joint contracture was now well recognised, and it was common to use early temporary pylons.

Discussion.

Mr. P. J. VERRALL said that coöperation between operator and limb-fitter was of the first importance. It was so at Roehampton. The Syme amputation was admirably suited to the native in the East, for he had no opportunity of wearing an artificial limb. In Europe, where artificial limb-making was so good, it was found that after six or seven years a Syme began to go wrong; the lower part divided posteriorly or to one side. The level at which bone was divided

and flaps made was determined largely by the scar. He did not like a posterior scar in a below-knee amputation; he had always used a postero-external flap. He felt contempt for spurs. Periosteum he divided on a level with the bone. Though for a long time he carried out drainage in amputation cases, for a year he had given it up. If he felt in doubt about a case, he stitched muscle with interrupted suture, especially in thigh stumps, but not closely. Splinting of the knee for below-knee amputations was important. No dressing was done until the fourth day. No hæmatoma was ever stopped by putting in a tube; it was rarely necessary to evacuate; a small hæmatoma was usually absorbed.

He insisted on the importance of remaining in bed for three weeks after amputation. He treated nerve-ends similarly to Mr. Page; he did not pull them down much, and certainly he would not avulse them. When circulation was unsatisfactory, it was generally because the stump was too long. When bursæ formed on the stump he advised leaving them alone; cutting a bursa out produced a scar, and that was liable to be rubbed into a sore. Faced with unsatisfactory arm stumps the surgeon should not indiscriminately remove all nerve bulbs, but only when a complaint of tenderness was made. Plexuses and nerve roots should not be interfered with. The upper limb was to some extent a sense organ; most of the pain felt in a stump was of central origin, the brain had little to do, and the importance of fitting an artificial limb early was that it gave the patient an objective. Experience at Roehampton was against disarticulation at the shoulder-joint for shivering arm stumps.

Mr. R. D. LANGDALE-KELHAM said it had been on the principle of trial and error that in this matter of limb-fitting after amputation definite facts were established. The civilian population was largely in the hands of the limb-makers, some of whom were good, others lacked anatomical knowledge. Many amputees were suffering unnecessary discomfort. The ideal above-knee stump for a prosthesis was one at the great trochanter, and for this type two forms of limb were available: (1) the American or central knee control; (2) that depending for its action on a special type of pelvic band and knee connexion. Under-support was better than over-support, for the patient was encouraged to develop his own powers. It was better as a rule to leave neuromata alone, but removal might enable a limb to be fitted. Sooner or later every stump over 12 inches in length would develop circulatory troubles, requiring eventually reamputation; he was not referring to disarticulation at the knee, but to the Stokes-Gritti operation. He had a strong dislike of the Syme amputation, though admittedly the Syme stump was a powerful one. Its average life, however, was no more than ten years. Callosities formed sooner or later in every Syme stump, and became very painful; sometimes they were actually in the scar. The ideal site for a below-knee amputation was 6 to 7 inches below the knee. The surgeon's responsibility did not cease when he had sent the patient, with or without a prescription, to the limb-maker; he should assure himself that the man had a limb which fitted his stump properly, and was one he could make use of. Moreover, the limb-maker required surgical advice and supervision. At Roehampton it had been found that the better the limb-maker the more did he welcome the surgeon's coöperation.

Captain A. R. MAXWELL said there were three factors to consider—the surgical, the technical or mechanical, and the psychological—and these could not be considered apart without harm to the patient. It was much simpler to provide an artificial limb for the lower extremity than for the upper, for the arm was a more complicated piece of mechanism with its requirements of flexion, extension, abduction, adduction, pronation, supination, and ability to grip. A stump might be surgically good but prosthetically bad; if prosthetically good it could not be surgically bad. The surgeon should plan his amputation to

accord with the prosthesis to be fitted, and give use and comfort. Some of the younger men studying for the Fellowship came to Rochampton to learn the use of appliances. There could be no standardisation in these matters; each patient presented his own peculiar problem for solution. In his own case the arm stump was less than 3 inches long, yet he could dig, plough, and use tools for wood and metal work. He emphasised the value of the will to succeed.

A demonstration was given of fitting artificial limbs.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

A MEETING of this Society was held at Sheffield on Feb. 28th, Dr. J. W. BURNS, the President, being in the chair, when a discussion took place on a paper read by Mr. W. W. KING (Sheffield), at the Manchester meeting on Jan. 24th, entitled

THROAT INFECTIONS AS AN ÆTIOLOGICAL FACTOR IN PUERPERAL SEPSIS.

Mr. King in this paper suggested that hæmolytic streptococci can be conveyed to the genital tract of a parturient woman by "spraying" from the throat of an attendant. In his view faulty antiseptic methods could not be the sole cause of puerperal sepsis because the rate had not fallen during the past 20 years in spite of the almost universal use of antiseptics, and because puerperal sepsis occurs in "born before arrival" cases, in hospitals in spite of every care, and in the private practice of even the most careful doctors and midwives. Hæmolytic streptococci, recognised as the chief cause of serious puerperal sepsis, were a frequent cause of diseases of the upper air passages, especially during the winter months, when the mortality from puerperal fever from all causes was highest.

The rate of admissions to the septic wards of the maternity hospital (the Jessop Hospital for Women), where Mr. King's investigations had been carried out, was constant more or less throughout the year, but hæmolytic streptococcal infections were more prevalent in the winter. Infection from the attendant's hand during this season was unlikely, since the organism was so easily killed by the simplest antiseptic methods. Moreover, of hæmolytic streptococcal infections in the cases under review the natural labours without interference had a higher percentage (46.5 per cent.) than either operative deliveries (34.6 per cent.) or abortions (5 per cent.). Mr. King gave reasons for doubting the possibility of prenatal infection of the vagina or of autogenous infection.

Kanter and Pilot had been the first to suggest in 1924 that puerperal infection could be "sprayed" from the throat of an attendant on to a woman in labour. Mr. King gave case records of 24 cases of puerperal sepsis from hæmolytic streptococci, of which all but three had spontaneous labours, in nearly all of which carriers were found among the contacts. One epidemic stopped when the use of masks was instituted. The conclusion reached by Mr. King was that the spread of hæmolytic streptococcal infection from the throats of "carriers" to parturient women is an important factor in the ætiology of puerperal fever which requires an extensive and co-ordinated investigation from every angle. On the assumption that this theory was correct he suggested as prophylactic measures: (1) the use of masks for all examinations which exposed the vulva of the patient, either during labour or for post-partum nursing; (2) a pregnant woman who had been in contact with anyone suffering from a sore-throat should have her throat and vagina examined for hæmolytic streptococci; (3) nurses with even slightly sore-throats should be excluded from maternity wards; (4) patients with sore-throats should be isolated; (5) at the first onset of pyrexia a vaginal or cervical swab should be examined for hæmolytic

streptococci, not only in order to treat the patient but also to give early warning of the possible presence of a "carrier." Local authorities should seek out "carriers" in connexion with every case of puerperal fever.

Desirability of Wearing Efficient Masks.

The PRESIDENT described two small epidemics which had occurred in a well-equipped hospital of 15 beds; in the first outbreak two, and in the second three nurses had the hæmolytic streptococci in their throats. He had not endeavoured to trace evidence of close association between the carriers and the cases which developed pyrexia, but had no doubt in his own mind that the infection took place during the early days of the puerperium in both epidemics, rather than during the actual labour. This was to some extent supported by the fact that since gloves and masks had been adopted in the wards no similar cases had occurred. Mr. King had focused attention on the hæmolytic variety of streptococci, but the President thought that the non-hæmolytic type which were present in the throats of several nurses in both the epidemics noted by him were also capable of producing a virulent infection in the puerperal woman. They had to guard their patients against all organisms which might be present in the throats of any of the attendants. The whole question of lying-in ward technique required reorganisation and readjustment. At present very stringent rules were made for the labour ward, caps, masks, gowns, &c., were insisted upon, yet within 12 hours of the baby being born the mother had her vulval toilet carried out by a junior nurse who wore neither a mask nor gloves. He asked Mr. King whether the masks usually worn at operations were a sufficient protection to the patient, and whether he had any experience of treatment by streptococcal antitoxin.

Prof. W. BLAIR BELL (Liverpool) agreed that streptococcal infection was often conveyed to patients from sore-throats. Preparturitional vaginal infections by streptococci were not autogenous, but resulted from the introduction of organisms from without. He had called attention to the danger of late coitus in this respect at the Obstetrical Congress in 1925. The acidity of the amniotic fluid (pH about 5.5) made it a valuable antiseptic douche from above. The increased dangers of operations after the escape of the fluid might be explained in this way. Infection might be carried into lying-in wards by visitors. If it was impossible to exclude them, their numbers should be strictly limited. Infection might be carried from one patient to another by bed-pans.

Prof. MILES H. PHILLIPS (Sheffield) was convinced that sprayed streptococci were a very real source of infection of women in labour or recently delivered, and welcomed Mr. King's paper. Dame Janet Campbell had given details of several small epidemics associated with nose and throat carriers of the hæmolytic streptococcus. He referred to experience gained in general and especially abdominal surgery, which had led the great majority of surgeons to insist on the use of a face mask, and gave examples from his own practice of the desirability of using efficient masks. Those made of a single thickness of butter muslin had been shown by bacteriological tests to be quite ineffective. A mask of four thicknesses of surgical gauze (each of which was itself four-fold) was probably effective. Thirty per cent. of the fatal cases recorded at the Congress on puerperal sepsis in London in 1925 occurred after a normal labour, and in 65 of the 256 cases investigated by Dame Janet Campbell in 1921-25 it was said that no internal examination had been made.

The Need for Further Controls.

Mr. LEITH MURRAY (Liverpool) considered that further control experiments were necessary before fully accepting the "droplet infection" theory as conclusive. He did not think that the wearing of masks would lead to any reduction in the incidence of sepsis, and went on to relate briefly two cases of puerperal morbidity which had occurred in a hospital.

The first of the series was subsequently proved to be a case of scarlet fever. Of the 15 attendants in this hospital, six had positive swabs from the throat of hæmolytic streptococcus, and in his opinion this incidence was the result rather than the cause of the morbidity in the scarlatinal case.

Prof. J. S. C. DOUGLAS (Sheffield) pointed out that the difficulty of identifying strains of streptococci should not be allowed to hamper the search for carriers of the organism responsible for puerperal infection. The fact that a certain proportion of pregnant women harboured hæmolytic streptococci in the vagina or cervix without developing trouble, rendered the effect of the introduction of hæmolytic strains by carriers the more noteworthy. Mr. King's thesis, though not proven, afforded such strong evidence that it was worthy of serious attention and would form an important basis for the further attack on the problem of puerperal infection.

Mr. W. GOUGH (Leeds) thought that all throats contained streptococci and that another factor besides this must be looked for.

Mr. A. GOUGH (Leeds) said that the reason why the morbidity-rate had not fallen was possibly due to a greater proportion of primigravidae than in the earlier returns of the Registrar-General.

Some Criticisms.

Mr. J. ERIC STACEY (Sheffield) whilst considering that every possible channel by which infection could enter ought to be closed, and advocating the use of masks, said he was not convinced that this mode of entry was the main route by which the organisms were introduced. Mr. King claimed only that spraying from the throat was one method by which the infecting organisms could obtain entry; all would accept this, but it should not be allowed to cloud other issues, for example, why in certain cases puerperal sepsis should develop and in others fail to appear. The number of women subjected to the spraying from the throat of an attendant who developed no sepsis was vastly greater than that of those who did, and yet the organisms had an equal chance of introduction. He agreed with Mr. Murray that further controls were necessary. It seemed unlikely that "throat spraying" could occur except from persons actually delivering the patient or the nurse doing the subsequent vulval swabbing. Epidemics of hæmolytic streptococcus infection occurred in gynæcological cases from time to time where all wore masks in the theatre, and where the infection occurred only in a small proportion of patients. A large number of cases arose in which hæmolytic streptococci are not the causal organism, and a few in which the throat could not be the source of infection—e.g., *Bacillus aerogenes capsulatus*. He had recently investigated for another purpose a series of 152 cases of "failed forceps." Twelve of these cases died from puerperal sepsis, but the hæmolytic streptococcus had been isolated from only three of them. In three cases gas-forming organisms were found and in the remaining six non-hæmolytic streptococci. Trauma, associated with an exogenous source of infection, such as faecal infection, was a factor which must not be lost sight of.

Prof. A. M. CONNELL (Sheffield) thought the individual herself must have hæmolytic streptococcus in her throat if throat infection was to be accepted as the causal factor.

Dr. J. A. STIRLING (M.O.H., Chesterfield), while expressing alarm at the thought that this method of infection might be so prevalent, considered the isolation of contacts in hospital almost impossible. He thought co-operation was necessary between family doctor, hospital, and public authorities.

Reply.

Mr. KING said that he had been careful to state that he did not exclude other sources of infection. It was premature to attempt to grade the importance of his theory in the causation of puerperal fever. He was satisfied that he had produced sufficient evidence to satisfy reasonable people that this avenue of infection must be closed. It did not seem much to ask that

obstetricians should adopt the same care for their maternity cases as they did for their gynæcological operations. In regard to controls, Mr. King suggested that the best test of the value of the theory would be the results obtained by the use of masks during the next five years, especially in maternity hospitals. He was confident that if the scheme was conscientiously carried out, puerperal fever in "booked" cases in maternity hospitals would be as rare as suppuration in laparotomy wounds. In anticipation of the objection that a large proportion of the population had hæmolytic streptococci in their throats during the winter months, Dr. Kirk, at his request, had examined swabs from the throats of 50 out-patients taken at random during the month of February, and only one was found to be a carrier. These results confirmed those given in his paper. As Prof. Douglas had said, final proof of the identity of the streptococci in the carrier and victim could only be obtained when accurate classification of hæmolytic streptococci was possible. Almost any organism could be carried to the patient in this way, including anaerobic organisms, which are well known to be occasional inhabitants of the throat. Mr. King found it easier to believe that *B. aerogenes capsulatus* could get into the vagina from the throat of an attendant than that it should get in on the doctor's hands or instruments. In regard to "autogenous" infection, he accepted Prof. Blair Bell's definition. There was surprisingly little positive evidence in favour of preparturitional infection as a cause of puerperal fever. In the scarlet fever case quoted by Mr. Leith Murray the patient might have been the victim of the attendant carriers. The relatively small number of cases of puerperal infection had been put forward as an objection to the droplet theory. The same objection was made to the contagion theory of Semmelweis. No more was known to-day than was known a century ago as to why only a few of those subjected to infection develop the disease. Infection from the rectum was improbable, since it so rarely followed gynæcological operations. He thought that masks made of four layers of butter muslin were probably satisfactory if not worn for more than two or three hours. He agreed that it was not always possible to exclude known carriers from the wards, and if so, reliance had to be placed upon masks. Great watchfulness was necessary to see that the masks were always worn for vaginal examinations and during the administration of enemata as well as for delivery and the subsequent nursing.

DONATIONS AND REQUESTS.—Mr. George Harding, of 164, Great Russell-street, London, left estate of the value of £18,015. He left the property in trust for his wife and his daughters during their lives, with remainder to the survivor for life, and on the death of the survivor as to one-fourth to Cheyne Hospital for Children, one-fourth to the Hospital for Sick Children, Great Ormond-street, one-half to Charing Cross Hospital, St. Thomas's Hospital, Middlesex Hospital, St. George's Hospital, Westminster Hospital, and the Royal Ear Hospital.—Mr. William Brown, of Inverclyde, Ayr, and West Nile-street, Glasgow, East India merchant, left, among other bequests, £1000 each to the Ayr County Hospital and the Royal Hospital for Sick Children, Glasgow; £500 each to the Glasgow Royal Infirmary, the Glasgow Western Infirmary, and the Glasgow Royal Cancer Hospital.—Mr. Thomas Hammett, of Chorlton-cum-Hardy, Manchester, who left £15,891, after a few bequests gave the residue of the property to the Royal Infirmary, Manchester; the Eye Hospital, Manchester; St. Mary's Hospital for Women, Manchester; Ancoats Hospital, Manchester; the Children's Hospital, Pendlebury, Manchester; Henshaw's Institute for the Blind, Manchester; and the Boys' and Girls' Refuge, Belmont, Manchester.—Mr. Frederick George Nutting, of Sutherland and London, among other bequests, left £1000 each to the Liverpool Royal Infirmary and St. Dunstan's Hospital for Blind Sailors and Soldiers.—Mr. James John Blundell, of London, left £5000 to the Freemasons Hospital and Nursing Home; £1000 each to the London Hospital, the Middlesex Hospital, University College Hospital, the Royal Free Hospital, the Royal Northern Hospital, the Brompton Hospital for Consumption and Diseases of the Chest, King Edward's Hospital Fund for London, Dr. Barnardo's Homes, and the National Institute for the Blind, besides other legacies.

PSYCHOLOGY.

The Process of Human Behaviour. By MANDEL SHERMAN, M.D., Ph.D.; and IRENE CASE SHERMAN, Ph.D. London: Williams and Norgate. 1930. Pp. 227. 12s. 6d.

This volume is frankly experimental and behaviouristic. That is to say, its exposition is based upon the thesis that human behaviour is exclusively the product of neural reaction to environment. The authors give a general account of nervous mechanisms, starting from the irritability of organisms to the structure and function of the human brain. They then describe in the manner of J. B. Watson the first human responses and also give their careful observations on the emotions of newly born infants. They conclude that there is a more or less quantitative relationship between stimulus and response. As can be well understood the thesis leaves little or no room for mind, and the whole study of personality and of social behaviour is based without relent upon the structure and function of the reflex arc and of the glands which govern emotivity. On this level of discussion the book is a good exposition of human behaviour, but for those who feel that the subtler reactions of man need something more than neural mechanisms for their explanation the thesis of the authors will not appear quite so satisfactory.

Psychology's Defence of the Faith. By DAVID YELLOWLEES, M.D., Ch.B. London: Student Christian Movement Press. 1930. Pp. 190. 5s.

This volume consists of series of lectures given before the Student Christian Movement, 1929; but have otherwise undergone little modification. The author, while being himself a practitioner of psychopathology, is also a man deeply imbued with religious feeling and faith. He has felt the need for bringing religion before the tribunal of psychology and psychology before the throne of religion. He has attempted to show that while psychology throws a profound light upon the religious life, it cannot do anything to alter the fundamental truths of religion or to diminish the glory of religious personages who have inspired mankind throughout the ages. He is deeply impressed with the views of Freud, but in so far as this pioneer is a Determinist, he feels himself more akin to Jung, whose philosophy allows for that human freedom which the religious life needs. The book is unfortunately marred by a certain colloquialism in expression which may have been necessary in speaking to students, but which rings unpleasantly in the ear when read in a serious volume.

"Just Normal Children." By FLORENCE MATER, Ph.D., Director of the Merryheart Schools, Columbia, Ohio. London: D. Appleton and Co. 1929. Pp. 294. \$2.50.

THE author has laid out her book on a plan which has brought out the extraordinary human side of this problem—the difficult child. She has described in a straightforward narrative way the lives of little children, their behaviour, their health, and their intelligence, stating how each was affected by some particular maladjustment, physical, psychological, or both. She tells how the subject of each disorder was studied empirically over a period of time, and how each disorder was corrected. The chapter ends with a series of questions arising out of the case, each question being answered with the wisdom derived from knowledge, common sense, and sympathy. The whole field of child guidance is explored, and the author has tried hard to make her observations and treatment clear to the non-technical reader. She does, however, give such ready answers to the questions which she herself has set that the book may give a false impression to the reader as to the ease with

which a maladjusted child is brought back to normality. The book may not satisfy all readers, but the value of the questions which are liberally sown throughout the book and of the case-histories is beyond dispute.

MANUAL OF PHYSICS.

Third edition. By J. A. CROWTHER, Sc.D., F.Inst.P. London: Humphrey Milford, Oxford University Press. 1930. Pp. 562. 14s.

As some seven or eight impressions of this manual have appeared its value cannot be called in question. The standard of the book is that of the numerous examinations which are coördinated by the Board of Education under the title School Certificate Examinations, including the revised Senior Local Examinations. The object has been to bring the principles of physics clearly before students, as the author's experience has shown him that a certain assimilation of facts is often not combined with a corresponding general appreciation of the subjects under study. The space devoted to mechanics remains, as in the original issue of the book, predominant, and all who have had any personal knowledge of the difficulties of students will agree that a full explanation of the properties of matter makes all instruction along further and more special lines much easier. The additions to the latest issue of the book will be found mainly in this section and under the heading of electricity.

IMMUNITY AND INFECTIOUS DISEASES.

By A. BESREDKA, Professor at the Pasteur Institute, Paris. Authorised translation by HERBERT CHILD, M.R.C.S., L.S.A., late Hon. Surgeon, French Red Cross; Capt. R.A.M.C. (T.Y.). London: Baillière, Tindall and Cox. 1930. Pp. vi.+320. 18s.

THIS is a series of 15 essays upon different aspects of immunity which Prof. Besredka has especially investigated during the past 30 years. They include a number of subjects, such as the bactericidal power of leucocytes, the bacterial haemolysins, the problem of the unity or diversity of the streptococci, &c.; but except for the first few chapters the general theme running through the book is the problem of the active immunisation of the individual, with especial reference to local immunity and local tissue vaccination. Briefly, the views of the author, which are now well known, consist in a disbelief in the importance of humoral antibodies, either as factors in or indices of the immune state, and a belief in the supreme importance of especially sensitive tissues, which by local treatment may be rendered immune, and thereby convey a general immunity. On the whole these essays are unconvincing. Many of them are only of historical interest, and it is difficult to know why they should be published to-day. We cannot believe that the distinguished author still holds that "the streptococcus met with in scarlet fever is not the specific agent—that to-day appears beyond a doubt." In many other respects the book is unsatisfactory. The reader who expects to find a reasoned, documented, and scientific exposition of Besredka's views will be grievously disappointed, and will gain the impression that the basis of his recent work is unsound and uncritical. Hardly any notice is taken of experiments or findings which are opposed to the author's views; practically everything quoted goes to substantiate them. The work of the translator does not add to the attractions of the book. His method of approach is so literal that French constructions appear on almost every page. Whilst a translator is bound to render faithfully the sense and meaning of the original, he is not debarred from the idioms of the language he is employing.

"The bodies of the bacilli emulsified in the physiological salt solution are placed in a cylindrical test glass, containing non-heated anti-plague serum, very agglutinant." "It was Theobald Smith who had this idea. In preparing

it he did not suspect, at the outset, that he was doing anything but realising a true sensitised vaccine."

These examples will illustrate the use of inappropriate English words which occurs on almost every page. Moreover, although "diastase" is loosely used in France for the whole body of ferments and enzymes, it is incorrect to translate the word literally when speaking of a hamolysin. Another word which also has a much more narrow meaning in English than in French is "virus," and yet we find it employed as synonymous with bacteria. On page 202 we find the expression "the stock or auto-vaccine."

The past work of the author has given him a deserved reputation in all countries, and many laboratory and clinical workers are anxious to evaluate his new and interesting theories. It is therefore unfortunate that this book will not give much help to those who are prepared to consider new ideas without bias.

ANIMISM, MAGIC AND THE DIVINE KING.

By GÉZA RÖHEIM, Ph.D. London: Kegan Paul, Trench, Trübner, and Co., Ltd. 1930. Pp. 390. 21s.

THIS is an addition to the now extensive literature of anthropology. The subject is dealt with under such general sections as animism and the psychology of magic, the medicine-man and the art of healing, the divinity of the king as successor to the medicine-man, and the sacrifice of the king as scapegoat for the sins of the people. The collection of native legends which the author has got together is remarkable alike for the width of its references and the repulsiveness of the episodes and examples set down. The section entitled the medicine-man relies for its facts largely upon the recorded habits of primeval races, but it is difficult to see how far these notes on savage life and scenes, even when recorded with some intention of consecutiveness, will be of any value to modern medicine. Serious psychological study, which is now so definitely associated with the study of medicine, is not likely to be advanced by any teaching conveyed by the book, although the habits and customs set down confirm much common knowledge as to the development of civilisation. The design has been to apply the modern principles of psycho-analytical research to explain the workings of the primitive mind.

ELECTROCARDIOGRAPHY.

Principles and Practice of Electrocardiography.

By CARL J. WIGGERS, M.D., Professor of Physiology, Western Reserve University, Cleveland. London: Henry Kimpton. 1929. Pp. 226. 30s. 6d.

THE advent of electrocardiography as a method of examination, the value of which has now received general recognition, sufficiently accounts for the large number of text-books devoted to the subject. A few of these are highly technical. The vast majority, however, are written for the practitioner. Indeed, as Prof. Wiggers expresses it in his preface, they are often content merely to give "arbitrary rules for turning knobs and closing switches.... with empirical directions for interpreting the records obtained." It is refreshing to find a book in which the author has struck out on a new line. As a physiologist with a leaning towards the physical side, Prof. Wiggers is able to speak with authority on the instrumental aspect of the subject. His book is primarily intended to give the medical practitioner a fuller understanding of the physical principles involved. The first hundred pages are devoted to general principles, and a full description is given of the various types of galvanometers in general use. It is perhaps unfortunate that the writer contents himself with describing these various instruments, and does not express any opinion on their relative merits and defects, but nevertheless this section

gives all the information which a cardiologist is likely to require on the technical side. The remainder of the book is devoted to a systematic consideration of normal and abnormal records. Typical examples are given of the various abnormal types of electrocardiogram commonly met with in practice; the analysis of the records is explained, the physiological and clinical significance of the disorders is discussed, and treatment is considered.

This book, written by a physiologist for clinicians, could with advantage have been published as two separate volumes. The presentation of the physical aspect is admirable, and without being too technical gives a very complete account of the subject. It will appeal essentially to the cardiologist who is interested in the scientific side of his work. The clinical section, however, is rather too elementary for him. It would serve well as an introduction to electrocardiography for the general physician or for the physiologist who is less familiar with clinical problems. The illustrations are excellent, and the general get-up of the book leaves nothing to be desired.

JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES.

Vol. XXVII. January-March, 1930.—Dr. Fergus R. Ferguson and Dr. Macdonald Critchley contribute a Clinical Study of Congenital Neurosyphilis, Part II., in which they record their observations on 36 cases, eight of which were congenital tabes, 12 congenital tabo-paresis, and 15 congenital general paralysis of the insane, while one was not classified. The clinical aspects of the cases are described and compared with some of the other cases collected from the literature. A useful bibliography is appended. —Dr. C. Worster-Drought and Dr. T. R. Hill report a case of Arrest of Physical Development (with Respiratory Dysrhythmia) following Epidemic Encephalitis in a boy aged 14, in whom the symptoms dated from an attack of epidemic encephalitis four years before. They suggest that the condition is due to the hypothalamic centres being involved to a much greater degree than occurs in post-encephalitic obesity and in the dyspituitary syndromes approximating to the Frölich type which occasionally follow epidemic encephalitis.—In a paper on the Treatment of Spastic Paralysis in Children, Dr. J. G. Johnstone, medical superintendent of the Heatherwood Orthopaedic Hospital at Ascot, maintains that much can be done by operation to alleviate spastic paralysis in a very large percentage of cases. He regards Stoffel's selective motor nerve resection as the method of choice in all cases, as it yields the best results, is always easy of application, and requires less prolonged after-care.—Dr. Jean Smith describes An Unusual Cardiac Malformation: Cor Triloculare Biventriculare with Mirror Picture Dextrocardia. The patient was a male infant, aged 36 hours, admitted to hospital with marked cyanosis and considerable respiratory distress. The apex-beat was in the fifth right intercostal space. No thrill was felt and no murmur was heard. Death took place 16 hours after admission and the condition described in the title was found at autopsy.—Dr. Hilda N. Stoessiger records a case of Recovery from Pneumococcal Meningitis with a review of the few other cases reported in the literature. The patient was a girl, aged 5 years, in whom the meningitis was secondary to otitis media. Organisms resembling degenerate pneumococci were seen in films of the turbid cerebro-spinal fluid, but no cultures of the organism were obtained. Recovery followed subcutaneous and intrathecal injection of 0.5 per cent. mercurochrome solution.—In a paper entitled Some Paediatric Eponyms II. Parrot's Nodes, Dr. Walter R. Bett gives a translation of Parrot's original description of the nodes in his *Maladies des Enfants* (Paris, 1886), followed by an account of his life and his other contributions to medicine, and illustrated by a fine portrait and a plate of a natiform skull.—The abstracts from current literature are devoted to dermatology and syphilis.

THE LANCET.

LONDON: SATURDAY, APRIL 12, 1930.

LOCAL GOVERNMENT AND HOSPITAL ACCOMMODATION.

THE Committee of King Edward's Hospital Fund for London has prepared a useful memorandum on the powers and duties of local authorities in the matter of hospital accommodation under the Local Government Act of 1929. Its form—almost a "counsel's opinion," drawn up by Mr. A. M. TRUSTRAM EVE—is significant of the complexity of the legal position. Indeed a further minor modification has already occurred since the memorandum was framed, as references to the Poor Law Act of 1930 (which received the Royal Assent on March 20th) must now be substituted for the corresponding references in the memorandum to the Poor Law Act of 1927. The chief changes which last year's Local Government Act brought about were structurally changes in the poor-law. Part I. of the 1929 Act was headed "Poor Law," and, as is now well known, the first step taken by the Act was to abolish the boards of guardians and to transfer the functions of all former poor-law authorities to the councils of counties and county boroughs. When, therefore, any attempt is made to explore the present powers and duties of local authorities for the provision of accommodation for the sick, there are three questions to be answered. What were the powers and duties of the former poor-law authorities which the Act has transferred? What were the powers and duties which the county and county borough councils already possessed in this matter? And what fresh powers and duties does the Act create? The answer to the first question is that boards of guardians had a general duty towards the sick, expressed in Section 34 of the Poor Law Act of 1927 (now Section 15 of the 1930 Act), "to provide such relief as may be necessary for the lame, impotent, old, blind and such other persons as are poor and not able to work." The guardians could pay for medical or other assistance required by such persons as the result of accident or sudden illness, they could subscribe to hospitals, infirmaries, or other, approved institutions receiving such persons; they could deal with maternity cases under their general powers of poor relief, and provision for infectious diseases (with which we are not at present dealing) could be similarly made under those general powers. Guardians, of course, provided workhouses; they could, if necessary, be ordered by the Central Department to provide "workhouse accommodation"—an expression which included hospital or infirmary accommodation. They have in point of fact established a system of sick infirmaries and sick wards in workhouses apart from their normal workhouse accommodation. Thus it comes about that the county and county borough councils take over a nucleus of separate infirmaries (virtually State hospitals), fulfilling a purpose far wider than their original narrow function as workhouses in the Elizabethan sense. These infirmaries not only supplemented the voluntary hospitals, they have also filled the gap where no voluntary hospital existed. The future working of the voluntary hospitals alongside these rate-aided institutions and the avoidance of wasteful competition or overlapping are objects

which the Special Committee of the King's Fund is particularly concerned to promote.

The second and third questions may be answered together. Outside London, as Mr. TRUSTRAM EVE observes, county borough councils, borough councils, and urban and rural district councils have the power (but not the duty) to provide for the use of the inhabitants of their districts "hospitals or temporary places for the reception of the sick." They could build hospitals themselves in their own or in other authorities' districts; they could contract for hospital accommodation or combine with other councils for a common hospital; and they could make reasonable subscriptions, not exceeding a penny rate, to voluntary hospitals by virtue of Section 64 of the Public Health Act of 1925. County councils (including the L.C.C.) had no power to provide hospital accommodation for ordinary illness or to subscribe to voluntary hospitals until Section 14 of the 1929 Act made this possible. The county council is now brought into line with the other local authorities already mentioned; the limit of a penny rate is increased by 33½ per cent. under Section 75 of the 1929 Act. Meanwhile the county borough, borough and district councils continue to exercise their functions in this matter as before; they continue also to exercise (with departmental sanction) the power to provide a temporary supply of medicine and assistance to poorer inhabitants under Section 133 of the Public Health Act of 1875—a power still denied to county councils. In London the metropolitan borough councils similarly continue to use their powers under Sections 75 and 77 of the Public Health (London) Act of 1891, unaffected by the 1929 Act, or by the fact that the 1929 Act gives similar powers now to the London County Council. The result of the transfer of poor-law functions is that county and county borough councils now possess alternative powers—powers which can be exercised as poor-law functions or as public health functions. The administrative schemes under the 1929 Act, according to Section 5 thereof, are expected to declare that various statutory forms of public assistance shall be made available exclusively under the statutes concerned rather than by way of poor relief. As Mr. TRUSTRAM EVE says, without a study of the administrative scheme it is impossible to appreciate the methods to be adopted by local authority in providing hospital accommodation.

One might add that the medical profession will also be considerably affected by the administrative arrangements whereby the local authority may delegate specific functions to committees and subcommittees. The thrusting of immense tasks of local government and public health over wide areas upon county and county borough councils will strain the machinery unless the main bodies are relieved by committees of much of their work. Committees and subcommittees will presumably have to deal with such matters as the general provision and management of hospitals and local medical services, the staffing and residential arrangements of hospitals, discipline and patients' complaints, medical education and training, and facilities for research. Much will turn upon the experience and outlook of the committeemen to whom these matters are entrusted. There remains another vital task of negotiation. Under Section 13 of the Local Government Act of 1929 (now replaced by Section 8 of the Poor Law Act of 1930), before the local authorities make their final arrangements they must consult "with such committee or other body as they consider to represent both the governing bodies and the medical and surgical staffs of the voluntary hospitals providing

services in or for the benefit of the county or county borough as to the accommodation to be provided, and as to the purpose for which it is to be used." The intention of Parliament is clear enough, but the fulfilment will be far from simple.

AMPUTATIONS AND ARTIFICIAL LIMBS.

A VALUABLE feature of the discussion on amputations and their relation to the artificial limb reported on p. 807 was the opportunity given to surgeons and limb-makers to exchange views upon their common task. Patients were also present, chosen to illustrate how by combined efforts a limbless man could be made comfortable in his appliance while regaining much of his former mobility and force. It was stated that in this country 50,000 people had limbs amputated as the result of the war, and the knowledge gained by surgeon and limb-maker in the handling of this crippled and maimed population has resulted in a revision of values. In the early days of the war most of the well-known classical amputations were accepted as standard operations, and none seemed more secure of its place than Syme's amputation. But now that more than ten years have elapsed since the conclusion of hostilities, the time is ripe for an assessment of end-results.

One outcome of the experience which has been gained is that an end-bearing stump in the lower limb is regarded unfavourably. Mr. MAX PAGE, who introduced the discussion, said that those who had seen numbers of cases would agree in condemning Syme's amputation, since a large proportion of these stumps did not bear the test of time, and in any case could only be fitted with a clumsy prosthesis. He had seen many Syme's amputations which had given good service, but had been obliged to reamputate others which were painful and had no functional value. Mr. JENNER VERRALL, from his experience at Roehampton, also condemned the Syme's amputation, as did Mr. LANGDALE-KELHAM. The end-bearing thigh stump, such as the Stokes-Gritti, was also deemed undesirable, but was said to be still popular in America, Canada, and Germany. In below-knee amputations, the most satisfactory stump was agreed to be one preserving 6 or 7 inches of the tibia, although even with 4 inches control of the knee could be obtained. For above-knee amputations, section of the femur about 4 or 6 inches above the level of the knee-joint seemed to give the best functional results when an ischial-bearing prosthesis was fitted. Mr. MAX PAGE deprecated the custom of pulling on the nerves at operation and cutting them high up because of the danger of post-operative pain. It was best to crush and cut them about an inch above the level of bone section and inject absolute alcohol into the nerve-ending. Some surgeons, when amputating through the thigh, inject absolute alcohol into the sciatic nerve at an early stage, thereby producing a nerve block which diminishes the operative shock as well as lessening the prospect of post-operative pain. Emphasis was laid on the necessity of maintaining good tone in the muscles of the stump during the convalescent period and of avoiding joint contracture. It is obviously easier to fit a purposeful artificial limb to a stump with well-functioning muscles than to one with poor muscular control. During the war period considerable attention was paid to the cinematic amputations of Vanghetti, where muscles and tendons were more directly employed in the manipulation of appliances, but apparently this type of operation is now seldom performed, either because the results are uncertain

or because of improvements in the artificial limb. There can be no doubt that for the successful reconditioning of a man with an amputated limb there must be complete coöperation between patient, surgeon, and limb-maker. Captain A. R. MAXWELL, who took part in the discussion, stressed this team spirit and added that "A stump might be surgically good but prosthetically bad; but if it was prosthetically good it could not be surgically bad." Each patient presents a peculiar problem; if the surgeon plans the amputation to accord with the prosthesis to be fitted, and the patient coöperates with goodwill, success should be assured. Captain MAXWELL in his own person provides an example of successful team-work; he has an artificial left arm, and although the stump is less than 3 inches long yet he can dig, plough, and use tools for wood and metal work.

The discussion has served a useful purpose in placing before the profession authoritative views upon amputations and their relation to the artificial limb founded on prolonged experience. If regret is felt that certain time-honoured amputations have failed to maintain their traditional place in surgery, it must be remembered that this failure is only in response to technical requirements far more exacting than those formerly made. The artificial limb has been improved out of all recognition in mechanical detail and in convenience. Only those who have to wear an artificial limb know the great comfort of a light appliance, and the light metals have provided the makers with material for a strong limb of little weight. Until the war the question of amputations was largely academic; surgeon and limb-maker worked in isolation, and little progress resulted. Indeed on the continent a type of artificial limb frequently fitted was of the same pattern as that originally designed by AMBROISE PARÉ in the sixteenth century. The advance made during the last dozen years or so in treating the limbless and providing for their comfort and usefulness is manifest.

CONTROL OF MEASLES.

MEASLES, whooping-cough, and diphtheria head the list of lethal acute specific infections of young children. Diphtheria ranks third and may, if the community so desires, virtually cease to rank at all; an efficient method of prevention is available for the asking. Of measles it might almost be said that it is one disease for the rich and another for the poor. Measles in the nursery entails as a rule a few days of discomfort and confinement, made up for by a subsequent enlargement of liberty at the seaside. Measles in the tenement house or slum dwelling is very different. The biennial epidemics in the great industrial centres result in the loss of many lives of young children (witness the Registrar-General's weekly return just now) and in permanent damage to an unknown but certainly very great number more. In a recent study reported to the Medical Research Council (Special Report No. 120) J. L. HALLIDAY established some important facts in the epidemiology of measles. He found quite definitely that in the tenements selected (in Glasgow) children were exposed to measles at the earlier ages of life, the period when the case fatality is highest. Although throughout Great Britain measles is essentially a disease of childhood, the period of child life in which an attack takes place varies. Among crowded tenement quarters the disease mainly attacks children under school age; in working- and middle-class families, who live in houses of the single-entry type, the disease is predominantly one of scholars from the age of

5 to 10 years. Among the public school class the age of incidence seems to be postponed to a still later period of school life. A. I. SIMER¹ regards it as an unfortunate result of the present precautions taken to prevent the introduction of infectious disease into boarding schools that a great number of boys pass through private schools without having contracted measles. Similar precautions in the public schools lead at length to a really great and serious epidemic involving overcrowding of the school sanatoriums; as a result of which complications arise which, in his experience at Rugby, turned an epidemic into a nightmare. G. E. FRIEND, from his experience at Christ's Hospital, finds that the isolation of infectious diseases combined with the exclusion from school of known contacts had the result of reducing the number of epidemics, but of increasing the number of boys infected when the epidemic did occur. SIMER and FRIEND would thus prefer measles to break out in their semi-isolated communities on a smaller scale at more frequent intervals, and having regard to the age-groups and stamina of the boys under their care no doubt they are right. For the public school probably the best thing is to let measles take its course, little and often. Not so, however, in the tenement, where younger children are concerned. HALLIDAY estimates the case-mortality for ages from 0-2 years as 10 to 20 times greater than for ages from 5-10, and so on in decreasing (but still excessive) ratio for ages up to 5. The reason of course is the greater incidence and fatality of broncho-pneumonia amongst the youngest age-group. What is the nature of this complication we do not know. According to DEBRÉ and JOANNON the virus of measles lowers the threshold for other infections; they regard the broncho-pneumonia of measles as a super-added specific infection. Broncho-pneumonia itself, a disease of the very young under-nourished child living in a crowded sunless environment, is sufficiently bad; as a concomitant of measles it is too often overwhelming.

A measles epidemic arises and attains its maximum incidence with great rapidity. Sir JOHN ROBERTSON, discussing a measles epidemic in Birmingham in 1908-09, showed that before the epidemic there occurred 31 deaths from measles in 20 weeks, during the epidemic period (January-May) 476 deaths in 20 weeks, and in the subsequent 20 weeks, the period of decline of the epidemic, 67 deaths. During an epidemic a large proportion of exposed susceptible children suffer an attack of frank clinical measles. The survivors attain solid active immunity as the result of the clinical attack. But HALLIDAY, from observations in the field, and P. STOCKS and M. N. KARN, as the result of the statistical analysis of the St. Pancras material independently deduced the development by some children during an epidemic of "a partial and probably temporary immunity" (Halliday) or "latent immunisation" (Stocks). Dr. Stocks has further developed his views of the mechanism of an epidemic in our columns this week, and we commend this paper to careful study. Clearly there occurs during a measles epidemic what S. F. DUDLEY has shown to be the case for diphtheria, an epidemic of immunisation. Whether a child becomes solidly immune as the result of a clinical attack, or partially and temporarily immune, depends upon what DUDLEY calls the velocity of infection. The practical result would appear to be that some exposed children escape

clinical attack in the first epidemic. When the next epidemic phase occurs they are in better case to withstand a clinical attack, not only because they are somewhat older, but also because they possess some degree of basal immunity. Unfortunately, it is impossible to control this epidemic of immunisation; in everyday life there is no means of regulating the velocity of infection. Owing to the characteristics of measles in the individual and in the community, notification as a means of control has been found to be of little value. Even if the requisite number of beds were available, and the public could be induced to regard measles sufficiently seriously to make full use of them, it is useless from the point of view of prevention to isolate a case which is only notified when the rash has appeared. At this stage, the maximum phase of infectivity—the catarrhal pre-exanthem or Koplik spots stage—has passed and the damage to the contacts by droplet infection has been done. Much useful curative work can be and is being accomplished in London and several provincial cities by hospital treatment of the severe cases or of those taken from the worst environment. Manchester provides for the notification by the practitioner of the first case occurring in a household; other cities have a system of partial notification through schools. The cases so notified are followed up by health visitors who offer general advice as to precautions to be taken, and sometimes by providing the services of a district nurse and essential nourishment. All such measures, useful as they undoubtedly are, only touch the fringes of the measles problem in industrial areas.

From the laboratory standpoint the position remains much as it was set out in J. E. MCCARTNEY'S review² three years ago. But while experimental research languishes, the clinical results of employing adult convalescent serum or whole blood for the attenuation of the disease in exposed susceptible children are being increasingly established on the Continent and in the United States of America. We have recently³ endorsed the procedure of injecting parental whole blood as one available for the family doctor. In their admirable monograph, from which we have already quoted, DEBRÉ and JOANNON tell us that the serum of adults who have had measles in childhood contains immune bodies not only against measles but against several other infections. DEGWITZ, in 1920, employed whole blood in 1000 cases. W. H. PARK, of New York, after a rigorous trial lasting 10 years, now advocates⁴ the use of parental whole blood. Dr. STOCKS, from a profound knowledge of epidemic measles in a London borough, believes that even without isolating the virus we ought to be able to devise some simple method of partial and temporary protection which would prevent the distressing features of the biennial epidemic. It is clear that except under special circumstances, where even a modified attack of the disease is contra-indicated, sero-attenuation—which results in a lasting active immunity—is preferable to sero-prevention, which confers passive immunity valid for a month at most. The basic causes of the high mortality of young children from measles are doubtless to be sought in poverty, in an improper dietary deficient in vitamins, and in overcrowded sunless dwellings. These conditions must be ameliorated. But that will take time and meanwhile it is certain that sero-attenuation amongst susceptible contacts will save many lives. The children in the family most likely to

¹ THE LANCET, 1926, II., 1057.² THE LANCET, 1927, I., 92.³ Ibid., March 8th, p. 519.⁴ Med. Officer, March 1st, 1930.

be attacked first are those of school age. Notification of the occurrence of measles amongst these might with advantage be followed by the prompt injection of those members of the family below school age, the aim being not prevention but attenuation.

Annotations.

"Ne quid nlmis."

ECONOMICS OF TUBERCULOSIS COLONIES.

At the annual conference of the Tuberculosis Association, held in Oxford last week, a report of which will be found on p. 804, a session was devoted to a consideration of the tuberculosis colony and village settlement. The day has gone by when these institutions had to justify their existence on medical or sociological grounds. Almost every Continental text-book on the antituberculosis campaign contains an account of Papworth, and it is the proud boast of that pioneer colony that no child born and brought up in the village has so far developed tuberculosis, though born of tuberculous parent or parents. The products of the various industries from village settlements have further demonstrated a high degree of skill and workmanship. But a tuberculosis colony like every other institution nowadays must either pay its way or give good reasons why it does not. Dr. Bardswell puts the matter tersely at Oxford when he asked "Why has no public authority undertaken a settlement?" Various specious answers could be supplied to this question. Public authorities in this country do not make pioneer efforts, nor have they been charged with possessing imagination. But Dr. Bardswell himself supplied the true one: "The financial position has never been clearly put before them." Writing in 1924, Dr. F. N. Kay Menzies said: "I am not in a position to give you any accurate figures with regard to either the Papworth or Preston Hall Settlements, but it is probably fair to say that the capital expenditure in each case is not less than £250,000. Apart, therefore, from the heavy annual cost of maintenance, it is difficult to see how the erection of a number of such settlements by local authorities could be justified as a practical proposition." This statement has found its way into at least one American text-book, but we are not aware that it has ever been verified or disproved by accountant's figures. The colony has hitherto been widely regarded as a luxurious and expensive method of dealing with the problem of tuberculosis and one which no public authority can face. As Dr. McDougall, medical director of the British Legion Village at Preston Hall, said at the conference the failure to put the financial facts before the public had done more than anything else to discourage the progress of village settlements.

The facts as he gave them are these. When the British Legion took over Preston Hall in 1925 the total initial capital expenditure, as estimated by a competent firm of valuers, was £38,970. Since that date money has been spent on developments which bring the capital outlay up to a round figure of £100,000. Dr. McDougall emphasised the importance of making the financial returns of a colony under the three separate headings of sanatorium, estate, and industries. Only in this way can the financial position be properly understood. In the sanatorium section at Preston Hall the accommodation has been provided at a cost of about £178 a bed, which, even when allowance is made for the fact that much of it consists of hostels and huts, is exceptionally low. On the maintenance side, Preston Hall has been able, in spite of the inevitable fluctuations of the bed list, to preserve a financial balance by charging local authorities £2 12s. 6d. a patient per week. In 1927-28 there was a profit of £105 and in 1928-29 one of £195. In the estate section the average cost per settler's house has been

approximately £403, and these houses are let at rentals varying from 4s. to 9s. per week inclusive of rates. Portions of the estate are also let to local farmers. The excess of income over expenditure on this section for the four years under review has been £978. In the industries section the total capital expenditure has been £17,544. At the moment, 145 settlers are earning their living at Preston Hall. The total sales during the four years period have realised £198,024; salaries, wages, and commission amounted to £66,160. The balance-sheet of this section shows an average loss per annum of £1080, or 1·8 per cent. on the turn-over. That is an average loss of £11 7s. 4d. a year per settler since the British Legion assumed control of the enterprise.

In our last issue Dr. E. L. Sandiland, medical superintendent of the East Lancashire Tuberculosis Colony at Barrowmore Hall, gave some figures illustrating the employment of ex-tuberculous patients in colonies, and showed that the breakdowns and time lost by the workers—2·2 per cent.—compared favourably with those in other communities. In spite of this, the colony has not yet reached the stages of a satisfactory balance. The last annual report of the colony states that there were then 25 settlers employed with a net loss in the industries section of £2479 18s. 8d. The Preston Hall figures suggest, however, that a loss in the industries section may be made up for by a profit in the sanatorium section, although at the moment there are no materials for a strict comparison between the losses on industries in one colony and those in another. Probably one of the advances likely to be made in the near future will be some agreed comparable system of keeping accounts. As time goes on, also, the size of a village settlement will presumably be adapted to the economic problem of the area it serves. Here the spade work done during the experimental years should prove invaluable. Dr. McDougall proposes accommodation for 200 patients in the sanatorium and 50 settlers in the industries section, and if such a ratio as this were found workable the hope of making ends meet with even a small margin for contingencies would be brought one step nearer. Be this as it may, it seems hardly fair at the moment to saddle the village settlements with all the responsibility of their deficits. Apart from the inestimable value of their work on the medical and sociological side, they contribute perhaps more than is realised to the relief of the burden of public authorities. Thus, Dr. McDougall pointed out that at Preston Hall one authority had at the present time 27 ex-patients in residence as settlers and the financial saving to that particular authority must be considerable. Again, there must be many tuberculous patients receiving more per annum from approved societies and disablement benefit than would be necessary to keep them at work as productive units in a settlement. And finally, the colony industries maintain their workers through bad times and good, and when, as recently at Preston Hall, untoward circumstances, such as a fire or breakdown in the works, throw the workers out of employment, they are not forthwith placed upon the dole, as they would be in many industries, but their maintenance is accepted as part of the liability of the industry. From the taxpayer's point of view, then, the colony is a better contribution to the tuberculosis problem than is often supposed. Colony finance has been described as robbing Peter to pay Paul; but Paul may prefer to be robbed by subsidising a man who can retain his self-respect by working four hours a day rather than by leaving him to be entirely unproductive. The immediate difficulties—namely, the capital cost of the settlement and the small percentage of the tuberculous population who are fit to avail themselves of its help—are enough to prevent public authorities from spending ratepayers' money in this way, but there seems no reason why the colonies, which are voluntary institutions, should not receive subsidies in proportion to the extent to which they relieve public authorities of their statutory obligations.

HEATING AND VENTILATION IN SCHOOLS.

In the severe weather of last year a number of elementary schools had to be closed on account of insufficient heating. This strange fact and others mentioned in the annual reports of school medical officers now coming in suggest that the problem of heating and ventilation in our school buildings is not yet completely solved. The first consideration in arranging a system of heating and ventilation must, of course, be the effect on the health of the school-children, although the cost of the method should not be unreasonably high. Complete guidance is not yet available but the introduction of the kanta-thermometer by Leonard Hill has made it possible to assess the condition of the air in schools in respect of warmth, humidity, and cooling power, of which up-to-date authorities like those of Torquay have not been slow to take advantage. Another source of information is to be found in an inquiry¹ just completed by the Industrial Health Research Board which deals more particularly with the comfort and efficiency of the pupils, and how these were affected by the cooling power of the air and the distribution of the heat, especially vertically. In this study the temperature of the head, hands, and feet were measured by an extremely sensitive Moll thermopile. It is generally recognised that for health and comfort the head should not be warm and the feet cold; in one of their experiments Dr. Vernon and Dr. Bedford show a 12 per cent. loss of manual dexterity when the hands were too cold. Two recent methods of heating were found to be good; one, the warmed floor plan introduced by Mr. G. H. Widdows in the Derbyshire schools, the other the so-called panel system. The former recalls the old Roman hypocaust system, but in the new system the pipes contain water under low pressure, whereas the Romans used hot air; the latter method has large cast-iron panels placed near the ceiling also heated by circulating water. With the panel system the temperature of the room at all levels is nearly uniform; with the under-floor pipes the feet are kept warmer than the head, giving a greater sensation of comfort. The panel system has the special merit that the heating is almost wholly radiant, while in most others, including the under-floor plan, it is largely effected by convection.

Comparative estimates of the health of the children under the two systems were not made directly in this research. Something might be gleaned from the records of absenteeism in cold weather, which were much higher in the less warmed schools, but, as the authors point out, the children were usually kept away not by ill-health but by the restraining action of their parents. The investigators were concerned with open-air and other schools; they hoped to apply the information to factory life, but they realise that the conditions are not strictly comparable. In open-air schools warmth is less important than fresh air and light; great benefit has accrued to weakly children in schools with little means of providing artificial heat, and at Hayling Island the heating has been reduced to the simplest imaginable form of coke braziers on the beach. The report states:

"Observations on the hand temperature of 117 children attending three practically unheated open-air schools showed that at two of them the temperatures were about 1° higher than those shown by children in artificially heated schools at equal cooling powers. Probably this was due to the fact that the children were specially fed, were warmly clothed, and they sat at work for short periods only, alternating with periods of physical exercise. By means of canvas blinds the cooling power of the air at open-air schools can be reduced to less than half that experienced in unprotected sheds. Nevertheless, the efficiency of the children, in very cold weather, is only about half that of children in heated schools."

In factories an even distribution of heat is essential for mental and manual efficiency and the fact that the

floor may be largely covered by machinery would rule out the under-floor system. For schools, the authors are inclined to think that the panel system is preferable to floor-heating except for open-air schools, but neither system is free from defect unless it embraces a small amount of hot-water radiators or pipe heating in addition to deal with the cold air from large windows. Useful rules suggested for the working of the heating (and associated ventilation) are that the temperature should not fall below 60° F. (or 55° as an absolute minimum) and the air never have a cooling power above 9°.

HEALTH INVENTORY OF NEW YORK.

The Welfare Council of New York has issued a 400-page volume on the machinery that has been developed to promote the health of New York's six million citizens. The report is written by Dr. Michael M. Davis, now director of medical services for the Rosenwald Foundation at Chicago, and Mary C. Jarrett, formerly chief of social service at the Boston Psychopathic Hospital, and has been prepared with the cooperation of 300 organisations (including the municipal department) engaged in health work in the five boroughs which make up New York. New York will learn for the first time its needs for health services, and how these needs are being met, and no doubt the future of health work in the city will be influenced by the facts disclosed. These health services are rendered mainly by clinics, by the home visiting of health nurses and social workers, by various publicity agencies, and by hospitals and convalescent homes, which engage in preventive as well as curative work. There are 818 health clinics in the city (excluding those engaged in curative work), and of these 68.3 per cent. are maintained by privately supported health agencies, 17.5 per cent. by the municipality, and 14.2 per cent. by other official agencies. The 160 clinics which deal with the pre-school child, mental hygiene, heart disease, and cancer are all voluntary institutions. Dental, venereal, maternity, and eye clinics are mainly private agencies. Only in the field of infant welfare does the municipality maintain more clinics than the privately financed agencies. The municipality, however, has accomplished a great work in the co-ordination of the agencies dealing with tuberculosis. Out of about 2,000,000 home visits made by health agencies, 800,000 were paid by health department nurses. It is estimated that 2,000,000 dollars are spent in clinic services, and 2,000,000 in home nursing services annually, and it is thought that New York spends less per head in this manner than other large cities in the U.S.A. It is also estimated in the report that for every dollar spent in this prevention work, 18 dollars are spent in curative work.

In a preface to the report Mr. William Hodson, the executive director of the Council, and Dr. Neva R. Deardorff, director of its research bureau, show that this study has been made possible by grants from the Rockefeller Foundation and the Commonwealth Fund, and that it has been arranged in such a way as to parallel the inquiry made into the work of the municipal health department in 1926 by the American Public Health Association. They point out that the inventory is primarily a quantitative description of existing health services, and that no attempt has been made to study and deal with the quality or effectiveness of the service. Dr. C.-E. A. Winslow, head of the public health department at Yale University, contributes an interesting foreword. The inventory, he says, makes it clear that the machinery provided is still insignificant in comparison with the real needs, and that the voluntary agencies in particular have been developed with little reference to local needs. The great needs for the future are better provision for pre-school and school-children, and improved quality in infant welfare work. A grave shortage of hospital and sanatorium beds is a striking defect in the tuberculosis programme. The important rôle played by the hospital in the

¹ A Study of Heating and Ventilation in Schools. By H. M. Vernon, M.D., and F. Bedford, Ph.D., assisted by G. G. Warner, B.Sc. Report No. 58. H.M. Stationery Office. Pp. 72. 2s. 6d.

development of clinic services of a preventive nature is highly significant. In nearly all fields coördination and standardisation of records and practices is called for, and there is an obvious opportunity to proceed further in the direction of generalised home visitation by a single district visitor in each neighbourhood. Dr. Winslow believes that future developments are likely to involve constructive leadership by the health department of a group of coöperative voluntary agencies rather than complete absorption of such activities in a tax-supported programme.

RELIEF OF BLINDNESS IN INDIA.

We print on p. 832 a letter from Lieut.-Colonel R. E. Wright I.M.S., professor of ophthalmology in the Madras Medical College, expressing a fear lest the leading article in our issue of Dec. 21st, 1929 (p. 1315), may create an incorrect impression concerning the relief of blindness and the teaching of ophthalmology in India. We are aware that the teaching of this subject in the large medical schools in India is now good; at Madras in particular the teaching is of a high order, for Madras has one of the finest eye hospitals in the world, and the University there has established a licence in ophthalmology while special ophthalmological centres have been started at other medical schools in the province and at Calicut. No doubt good work is being done elsewhere too; we mention Madras as detailed information happens to be available. The well-known work done in the past and still going on in the various Government hospitals and in other institutions did not come within the scope of our article, but it may be remarked that in the Madras Government Eye Hospital nearly 4000 in-patients and over 25,000 out-patients were treated during 1928. There, as in other centres, the number of in-patients was limited by the available supply of beds, and the total number of cases seen at Government hospitals and dispensaries alone must be enormous, irrespective of the other agencies. What we were trying to emphasise was that there is room for improvement in the treatment of trachoma, at least among the older medical men in India, and especially those who work in outlying dispensaries. Many of the latter are of the subassistant surgeon class, who in past years at least had a shorter course of training than the ordinary medical man, either in India or in Europe. The statement that the teaching in the ordinary medical curriculum in India (as in Europe) was scanty referred to the past, and an allusion to "refresher" classes in trachoma, given to qualified medical men practising in trachoma districts in Austria before the war, was coupled with the admission that the standard of teaching in ophthalmology in that country was high, expressly to avoid giving the impression that by suggesting such a course we were casting a slur on the present workers in India. Even in Madras, however, Colonel Wright himself has admitted that there is room for improvement in the treatment of trachoma.

"We try," he says, "to impress on the students and post-graduates the undesirability of making a diagnosis of 'granular lids' because there is a liability for anything and everything to be diagnosed as granular lids by the average doctor and even by those with special training in ophthalmology. The result of this is that throughout the districts the more energetic forms of trachoma treatment such as rolling, grattage, and the application of strong irritant remedies is freely indulged in, in the treatment of cases which would probably get well if left alone or treated by some milder and non-irritating remedies."

In certain parts of India at least the actual treatment of trachoma, even when correctly diagnosed, is capable of improvement in many cases, judging by the results seen. It is still the cause of much blindness and defective sight, and a well-planned "refresher" course, or any other practicable method of improving the treatment, would be of inestimable value to the

people of India. The diagnosis of trachoma involves an exact knowledge of conditions which may be mistaken for it.

FRESH LIGHT ON INQUEST PROCEDURE.

THE considered judgment in *Rex v. Divine, ex parte Walton*, delivered by the King's Bench judges on March 17th, is the most important pronouncement on inquest procedure for many years. The office of coroner is marked by ancient traditions which Parliament has never completely standardised. The big Act of 1887, replacing a series of statutes going back as far as the thirteenth century, contained an express saving for "established jurisdiction, practice or procedure or existing usage," but this saving clause is naturally difficult to interpret, especially in view of local diversity of practice. For example, when a coroner has recorded the evidence of witnesses, must he read his notes over to them before they sign? Many coroners adopt this precaution, but the recent judgment in *Rex v. Divine* declares that they need not do so. If a coroner thinks there is uncertainty as to what the witness has said, or if the witness requests it, the coroner ought to read over the deposition and the witness may be justified in declining to sign until it is so read to him. But the statutory requirement, set out in Section 4 (2) of the 1887 Act, merely directs that the deposition be signed by the coroner and the witness, and the judges have now pointed out that to insist on any further requirement would be adding something beyond what Parliament enacted. Again, need a coroner, when permitting a jury to view some object outside the court (such as a damaged motor vehicle), allow the parties to be present whose conduct is in issue? The judges now rule that he is not obliged to give the parties this opportunity; the matter is one for his discretion. Should the coroner accompany the jurors on these occasions? The judges say he is not doing wrong if he goes with them, but it is "probably better that he should not." If he does go, he must be careful to abstain from discussion. The principle is that, when evidence has been given in open court, it is entirely wrong that further evidence should be given informally outside the court, or that anyone (even the coroner himself) should join with the jury in the discussions preliminary to their verdict. In *Rex v. Divine*, a review of proceedings at an inquest in Hull (already described in *THE LANCET*, Feb. 22nd, p. 426), a police constable, who had already given evidence in open court, joined the jury in their inspection and pointed out to them certain matters which apparently had a crucial influence on their decision that the motorist must have been travelling at a high speed. This, say the judges, was most improper. This important information should not have been given outside the court; the incident was good ground for quashing the inquisition. The judges' opinion here, however, seems to justify the comment that, if (as is a not uncommon practice in all courts) a jury is allowed to inspect some object or place outside the court, the coroner should accompany them, although the judges have said that it is probably better that he should not. Somebody must accompany the jury on these occasions; unless the coroner goes himself he cannot be satisfied that additional informal evidence or argument is not being surreptitiously conveyed to them.

An instructive passage in the judgment concerns the selecting of a coroner's jury. It appears that at Hull—as indeed probably elsewhere—there is a practice of using a severely limited panel of jurors for inquest. Eleven jurors were summoned out of a total panel of only 16 or 17 persons. This practice, in a great city like Hull, the judges describe as very objectionable. The principle of the jury system, they say, is the determination of facts by persons taken at haphazard from the body of qualified persons; it is a breach of that system to have a small panel of "regular jury-men." The judges could not definitely declare the system of summoning jurors at Hull to be illegal. No Act of Parliament requires the coroner to have recourse to persons on the voters list from which other

¹ Report of the Government Ophthalmic Hospital, Madras, 1928, p. 17.

kinds of jurymen are drawn; the selection of a coroner's jury is largely in the coroner's discretion. Section 62 of the Juries Act of 1825 authorised coroners to continue to choose their jurors as theretofore accustomed. Indeed in itself the practice of using a limited list of jurymen is not necessarily reprehensible. The great Lord Mansfield, when laying down the broad lines of our mercantile law, is said to have relied habitually on certain merchants of proved aptitude and experience as his special jurymen at the Guildhall. Coroners' juries, as Hawkins J. once observed, must be brought together in haste and therefore cannot be summoned in the normal leisurely manner. The recent judgment is, however, a broad hint to coroners not to let their officers summon on every occasion the same handful of familiars. In this connexion the judges had to consider another point in the Hull proceedings. The coroner had, before the inquest, gone to view the damaged vehicle with a man who was one of the "regular jurymen" and was subsequently the foreman of the jury. The judges accepted the coroner's statement that no discussion of the causes or circumstances of the accident then took place, but they declare the incident to have been an irregularity which would technically have been "misconduct" even at common law and which justified the quashing of the inquisition as a course "necessary or desirable in the interests of justice" within the extended powers of the High Court under Section 19 of the amending Act of 1925.

It was not really needful that the High Court should have examined into the several matters of alleged irregularity in the Hull proceedings. Fresh evidence had become available since the original inquest had been held, and on this ground alone the High Court decided (a month earlier) that a new inquest should be held. No reflection was made upon Dr. John Divine, the coroner for the city and county of Kingston-on-Hull; an attack upon his summoning-up was held not to have been substantiated. Having become aware of the allegations of irregularity, the High Court had to take notice of them; thus, after summarily ordering a new inquest on the ground of the fresh evidence available, the judges took time to consider the other aspects of the case in the postponed judgment lately delivered. There is no need to dwell further upon the ancient and peculiar usages of the coroner's inquest, the wider terms of the oath administered to the coroner's jury, or the other matters which differentiate the inquest from the ordinary forms of criminal procedure. Clearly, any practices which damage the credit of the inquest as a judicial tribunal either in the eyes of the High Court or in public opinion will, if persisted in, challenge the continued existence of the office of coroner. A practice may not be forbidden by statute and yet may be open to considerable objection.

LIVESTOCK IMPROVEMENT.

Prof. F. A. E. Crew, addressing the Royal Society of Arts on April 9th, stated that the lag between demonstrated scientific fact and its incorporation into practice was usually about 20 to 50 years. It is, he said, of the first importance that genetical methods with a scientific foundation should be applied to livestock as quickly as possible if the country is to recover from the present depression in agriculture. A number of factors combine to hinder the development of comprehensive breeding schemes at present, not the least is the financial insecurity in which agriculturists are involved; they literally have not the capital to attempt new methods. Then, traditional wisdom is not readily shaken by new theories, and breeders will not reconsider lightly their old practices. Prof. Crew emphasised the need for establishing a standard of excellence at which breeding should aim, and this is not a simple matter. Sheep breeding, to take an instance, must aim at the production of good mutton as well as good wool; but the fleece of the more thriving sheep is not necessarily the best in the wool market; it is important to decide what qualities must receive primary consideration. The

habitat will also demand variations in the ideal type. Ignorance among the stock-breeders is responsible for many fallacies in present methods. Prof. Crew mentioned "those who sell the quickest growing sows and keep the slowest for further breeding, not knowing that the economical conversion of food into pig is an inherited character, and that the quickest growers are the most economical feeders." These, and similar mistakes, he considers can be avoided by the application of genetical methods by the breeders themselves, but this cannot be accomplished without better education of the breeders. Ability should be rewarded, but not as at the present agricultural shows, where emphasis is too often laid on the wrong points. He thinks that too much weight is given to pedigree and too little to the milk record, the bacon quality, the pulling power, the egg and the fertility records. The waste resulting from existing methods is not easily assessed, but he stated that 40 to 50 per cent. of all mares put to the stallion each year fail to produce a foal, and that about 50 per cent. of unfertile matings are due to genetic causes; sterility can be bred into a stock, and it is as important to breed for fertility as it is for any other valuable quality, a point too little realised at present. He concluded with some interesting suggestions on the potentialities of laboratory experiments if applied to agricultural stock. Ductless gland therapy might be used to determine the rate and limit of growth, the duration of lactation, the deposition of fat, and other qualities at present obtained only by the slow process of selective breeding. Research which has been carried out successfully on rats and mice promises to give the same valuable results with agricultural stock if the opportunity is forthcoming.

LOCAL SEQUELÆ TO RADIUM TREATMENT.

THE fact that radium has a more lethal effect on malignant cells than on normal ones is now generally assumed to be the basis of the treatment of cancer by this powerful agent. There are many other disorders, however, in which it is sought to profit by the differential action of radium on various types of non-malignant cell. One of the methods of studying the differential action of radium is to make careful observations of the nature of the local sequelæ to its use. Mr. N. Asherson¹ has noted among the 220 patients treated for non-malignant conditions at University College Hospital during the period 1921-23 the following sequelæ: (1) annular (hour-glass) constriction of the vagina; (2) atrophy of the portio vaginalis of the cervix; (3) shortening and stenosis of the vagina; (4) ovarian neuralgia. Up to 1927 the average dose of radium treatment per patient with a non-malignant pelvic condition was 1200-1800 mg.-hours, but during 1927 and 1928 bigger doses (above 2000 mg.-hours) were given in many cases. It was with the advent of these big doses that certain sequelæ came to light, mostly in women over 40. Among more than 200 cases treated with radium during the years 1921-27 annular (hour-glass) constriction of the vagina was not once observed, but it was found in two out of ten cases treated with doses varying from 2500 to 3000 mg.-hours of the element in 1927-28. In both cases this condition, which was detected within three to four months of the treatment, was associated with complete atrophy of the portio vaginalis of the cervix. The mucous membrane of the vagina was normal. The constriction, situated about one inch from the introitus, was apparently a fibrous ring which yielded slightly to firm pressure. Atrophy of the portio vaginalis of the cervix has been frequently noticed by Mr. Asherson in the routine examination of patients followed up. This atrophy may, however, be only apparent, depending on changes in the uterus and vagina. Complete obliteration of the vagina by

¹ *Ann. of Obstet. and Gyn. of the Brit. Emp.*, 1930, **xxxvii**, 81.

total stenosis and shortening of the vagina has been observed only in inoperable cases of carcinoma of the cervix, never in non-malignant cases, but chronic purulent and adhesive vaginitis have occurred. "Neuralgia" radiating from over both ovarian regions down the inner side of both thighs to the knee was complained of by one patient, whose general abdominal pain had ceased after radium treatment. One radium burn of the vagina was ascribed to the slipping of the radium tube. Mr. Asherson adds that no case of malignant disease has been recorded in a patient subjected to radium treatment for menorrhagia.

An extended experience in examining cases treated by radium has convinced him that the sole therapeutic action of radium—whether in non-malignant or malignant cases—lies in its being a stimulator and producer of fibrous tissue, and he claims that this theory is supported by the sequelæ observed. He suggests that should there be a few malignant cells, as in an early case, a big dose of radium producing much fibrous tissue may strangle all the malignant cells and so bring about a cure. Should some of the cells escape the effects of this fibrous tissue they will multiply and then overcome the fibrous tissue, and when this resistance is finally overcome the growth extends rapidly to its fatal issue. It is curious that in spite of the widespread use of radium the mechanism of its action is still a matter of dispute.

THE ACQUITTAL OF ETHYL PETROL.

WHEN an enterprising firm put on the market of this country a motor spirit containing a small quantity of tetra-ethyl lead, they encountered a considerable body of opposition. Alarm was expressed freely in the press and in Parliament lest the new fuel should liberate, if its use became general, a sufficient quantity of lead to endanger the health of the public, and the popular suspicion thus fostered had the unfortunate result of compelling the manufacturers to cease distribution before the question could be determined scientifically. The Minister of Health set up in April, 1928, a Departmental Committee which published an interim report in July of that year,¹ but their provisional findings, though favourable, were not sufficiently positive and did not attract wide enough publicity to counteract the popular prejudice against ethyl petrol. The final report of the Committee² states in the most conclusive terms that the general use of ethyl petrol—we are not concerned in this country with the manufacturing hazard—would involve no danger to public health whatever. Their experiments have proved that the quantities of particulate lead in the atmosphere would not be great enough to endanger the health even of drivers and of policemen on point duty. The ordinary London dweller inhales about one-tenth of a milligramme of lead in a day; the lead inhaled even by those most exposed would not exceed twice that quantity and would still be negligible as a source of danger. Moreover, the hazard from exhaust gases and spillage in a well-ventilated garage is equally minute, and even in badly ventilated garages is not serious; probably nothing like as serious as the risk of poisoning from the carbon monoxide which is common to the combustion products of all fuels. Even those whose skin would be constantly exposed to the liquid would undergo no danger, for it caused no ill-effects whatever even when applied continuously to the shaved skins of rabbits for four months. These results agree with those obtained in America, and amount to a discharge of ethyl petrol without a stain on its character, although, to make assurance doubly sure, the Committee recommend that the fuel shall continue to be dyed, that all cans and pumps containing it shall be labelled, and that the amount of lead tetra-ethyl should not exceed 1 part in 1300 by volume or 650 by weight. It remains to be seen whether, with this evidence at their back, manu-

facturers will reintroduce ethyl petrol. It undoubtedly has certain advantages and seems to harm engines as little as man, though its outstanding merits are chiefly apparent in engines with a much higher compression ratio than those of the ordinary motor vehicle. These are the points of interest to the motorist, but the report contains a wealth of accurate information (summarised on p. 826) on the apparent universality of lead, when sought by delicate tests, and on the processes of absorption and elimination which will engage the attention of the toxicologist and medico-legal expert.

THE SAFEGUARDING OF VOLUNTARY ASSOCIATIONS FOR MENTAL WELFARE.

WHEN the Local Government Act, 1929, came into force on the first of this month, the care of mental defectives was handed over to county and county borough councils. In this connexion the Ministry of Health have circulated a three-year scheme whereby the invaluable coöperation of voluntary associations concerned with the welfare of defectives can be retained by the new authorities. The Minister suggests that every Council shall pay two annual contributions—one to the local voluntary association and one to the Central Association for Mental Welfare. The amount of the contributions is prescribed by the schedule, and is to be paid in quarterly instalments. The efficiency of the local associations is made a condition of their grant, and is to be judged by the council who make it, while that of the central association is to be judged by the Minister. Local councils are entitled to inspect the premises and services of the local associations and to receive a copy of the annual report and statement of accounts. Except on the ground of inefficiency, no councils are entitled to terminate or reduce their annual contribution without the consent of the Minister. The contributions to the central association have been based on the Board of Control's direct grant of £2000 for the standard year and apportioned between the various local authorities according to population. By Section 106 of the Act local authorities can request the Minister to pay their contributions direct to the central association and, in view of the obvious inconvenience in collecting small sums quarterly, the Board of Control hope that all local authorities will take this course. The purpose of this scheme is to protect the voluntary associations under the new system; the amounts of the contributions may be varied from time to time, and local authorities can make further contributions if they wish to. The value of the voluntary work carried out in all parts of the country is so indisputable that it is to be hoped that the new organisation will in no way hinder its development.

THE house and library of the Royal Society of Medicine will be closed from Thursday, April 17th, to Tuesday, April 22nd, both days inclusive.

Summer Time will commence in Great Britain, Ireland, the Channel Islands, and the Isle of Man on Sunday morning next, April 13th, at 2 A.M., when the hands of timepieces should be advanced one hour. It will end on Sunday, Oct. 5th. France and Belgium will make the change at the same week-end, Holland on a date in May, while Spain has not definitely decided but will probably not adopt it at all this year.

Mr. Harry Percy Adams, who died on Monday in Westminster Hospital, was a great architect of hospitals. Head of the firm Adams, Holden and Pearson, which designed the new Royal Westminster Ophthalmic Hospital and is executing the large modern hospitals at Constantinople and Malta, he was assessor for the new Birmingham Hospital Centre which produced the admirable design recently printed in our columns. Hospital patients will have reason to remember Mr. Adams with gratitude, for it was he who introduced into this country the lengthwise lay-out of wards which combines comfort with privacy.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

LXVII.—BACTERIAL BLOOD CULTURES.

In many protozoal infections, such as malaria, parasites appear in the blood in such numbers as to be readily recognisable in a film. Few bacterial blood infections can ever be recognised by this simple technique, although very occasionally, as a terminal event, stained blood films show organisms in such infections as staphylococcal septicæmia. Cultural methods are therefore essential for the effective diagnosis of septicæmic infections in general.

It is generally accepted that the circulating blood of a healthy person is sterile. Organisms must constantly enter the blood stream, but in a state of health the bactericidal power of the blood, and the filtering property of the reticulo-endothelial system, almost instantaneously kill and remove them. It is probable that, even in severe septicæmia little actual multiplication of organisms takes place in the circulating blood. But a "positive" blood culture is usually evidence of a severe generalised infection and bears a correspondingly grave interpretation.

The terms "septicæmia" and "pyæmia" are in common use. There is little real distinction between them. Both imply a deficient bactericidal power of the patient's blood and reticulo-endothelial system; the formation of metastatic abscesses, known as pyæmia, is often a late stage of "septicæmia," and on the whole a sign of satisfactory local reaction. The terms are relics of the early days of bacteriology and will probably be abandoned in the future.

Indications for Blood Culture.

Blood culture is indicated in any case of unexplained pyrexia. Even with our present inadequate methods a surprisingly large number of positive blood cultures would be found if such examinations were more frequently made. The following list suggest certain appropriate cases for this investigation: (1) Patients with valvular lesions of the heart, with a temperature failing to react to salicylates. (2) Patients in the puerperium, with an unexplained temperature over 101° F. persisting more than 48 hours. (3) Patients with skin wounds, however slight, with a temperature over 101° especially if rigors are present. (4) Patients with severe sore-throats and rigors. (5) Patients recovering from surgical operations where a high temperature persists for more than 48 hours and exceeds 101°. (6) Any patient with a rigor, unless there be an obvious explanation (e.g., malaria, serum sickness). (7) Patients suffering from acute infections of the middle ear, including acute mastoiditis. Many patients with rigors, in whom blood cultures are not systematically performed (such as those passing urine per vias naturales after prostatectomy), will be found to give positive blood cultures if examined during the rigor.

It will be noticed that a temperature of 101° has been selected as a crucial one. This does not imply that all patients with this temperature are likely to have septicæmia, but it does imply that until that point is reached and in fact until the temperature reaches 103°, positive results are improbable.

Methods of Culture.

It is essential to recognise that while a positive blood culture is significant, a single negative culture is of no value. Even in severe septicæmia only a very few organisms are present per c.c.m. It is therefore necessary to take the cultures under optimal conditions, of which the most important is that the temperature of the patient should be at its height, or on its upward

curve. Positive cultures are most likely to be secured, for example, during a rigor. Study of the temperature chart will show that at some period, usually at night, the temperature is highest, and such occasions should be selected. Exceptional cases of septicæmia, usually severe if not fatal, are occasionally encountered in which the patient fails to react at all to the infection and temperature does not rise. But the majority of blood cultures taken in afebrile states are sterile.

The sterilisation of the skin is of great importance. Blood is most readily taken from the median basilic vein and the skin must be thoroughly cleaned with ether and painted with iodine.

The most satisfactory cultures are those taken at the bedside by a pathologist, the blood being directly introduced into the culture media. If this is quite impossible, blood may be taken, either with a syringe sterilised in boiling methylated spirits or by a Wassermann needle, into a sterile tube with a sterilised rubber plug. A tube (the "Behring venule") fitted with a needle, and already sterilised, is on the market, and blood is withdrawn into this through the agency of a partial vacuum. This is quite a satisfactory arrangement for the transmission of blood for culture. Coagulation may be prevented by a trace of potassium oxalate, or a f.c.m. of Liquor Trypsin Co. (A. and H.) previously sterilised by filtration. Citrated blood is useless owing to its alkalinity. The blood can then be sent by post for culture, but results are less reliable, if negative, than those in which the blood is directly applied to the culture media. The culture even of blood-clots, however, is often of value, especially in enteric fever and malignant endocarditis.

Not less than 10 c.c.m. of blood should be taken at any examination, and it should be sown in a selection of liquid media. Solid media are as a rule useless. It must be stressed that the culture of a few drops of blood from a patient's ear or finger is quite useless. In order to prevent coagulation trypsin solution is of great value. Bile-salts similarly prevent coagulation and are useful in enteric fever and similar diseases, but inhibit the growth of some bacteria. Among the best media are glucose broth and distilled water. Cultures are grown both aerobically and anaerobically, the bulk of medium being always at least five times as great as that of the blood. A positive culture is evidenced by turbidity and change of colour of the medium. Cultures are examined daily, and no culture is deemed sterile until at least 14 days have passed.

Results of Culture.

Contaminated cultures are common, the organisms being derived either from the skin or the air. From the skin staphylococci and diptheroid bacilli are commonest, and from the air organisms of the subtilis group. Of these only the staphylococci present difficulties; if only one tube of a serum contains the organism, and if the organism is of the "albus" type the cultures are usually held to be contaminated. Staphylococcal septicæmia is by no means uncommon, and blood cultures taken in the early stages of acute bone infections consistently give evidence of it. It is also frequently met with in severe infections of the subcutaneous tissues. But it is as well to withhold judgment if no organism other than the staphylococcus is demonstrated. Streptococci, on the other hand, are always to be accepted as evidence of blood stream infection, and are, with the typhoid group, the organisms most commonly found. Influenza bacilli, gonococci, and indeed nearly all recognised pathogenic organisms have at some time been reported, but are all in varying degree exceptional.

The discovery of organisms of the enteric group means that the patient has typhoid, or other analogous fever, cultures taken within a week of the onset of symptoms being regularly positive. They are probably the easiest organisms to grow from the blood stream. *B. typhosus* being easier to recover than members of the Salmonella group. Even within the first 48 hours of the illness positive cultures may be obtained, and, contrary to statements sometimes made, positive

cultures are obtainable so long as the temperature is raised; the likelihood of success diminishes after the first 14 days. Negative blood cultures at no time exclude these infections, and the importance of a white cell count, showing leucopenia, and an agglutination test after the first ten days, must not be forgotten.

The growth of *pneumococci* in pneumonia has no important clinical significance beyond confirming the diagnosis. In lobar pneumonia most authorities find that about 30 per cent. of cases give positive blood cultures, and it is suggested that these are more frequently found in the more severe cases. There is no general agreement on the question as to whether lobar pneumonia is a septicæmia which becomes localised, or a pulmonary condition with an overflow into the blood. *Pneumococci* are also occasionally found in blood cultures of subacute infective endocarditis, and in septicæmias following operation and post-mortem wounds.

Streptococci in the Blood.

The recovery of streptococci from the blood is of the greatest importance, and in a patient with a valvular lesion of the heart almost invariably implies the fatal diagnosis of malignant endocarditis. Few bacteriologists claim to have secured positive blood cultures in simple rheumatic endocarditis. In subacute malignant endocarditis the organism is usually *Streptococcus viridans*, and in the more rapidly fatal cases hæmolytic types are found. A hæmolytic organism therefore bears a worse prognosis. If no valvular lesion is recognised and streptococci are found, the diagnosis is one of septicæmia, and the prognosis again depends to some extent on the nature of the organism, since the hæmolytic strains are as a class the more dangerous. The localisation of infection in deep abscesses should be looked for, and is of good omen; but incisions, whether blood cultures are positive or negative, should never be practised until pus is beyond question present. It is quite common for large swellings to appear and disappear many times before true localisation occurs.

If a hæmolytic streptococcus is present, treatment with antitoxic sera is urgent and essential. There is as yet no final evidence as to the specificity of hæmolytic strains, and in this country the use of scarlet fever antitoxin has been found satisfactory in cases both of puerperal and other streptococcal septicæmias. While intravenous injection is, as a rule, harmless, it always causes rigor, and the intramuscular route is preferable. At least 30 c.cm. should be given in one dose, and up to 100 c.cm. may be given without fear of bad results, and repeated daily. Such heroic doses may appear excessive, but recovery has been observed in apparently hopeless infections when they are employed. In pneumococcal septicæmias therapeutic sera are also available, and in the hands of many authorities have yielded good results. In the rare cases of meningococcal meningitis the appropriate serum should always be used.

In septicæmias other than these there is no indication for specific treatment at present. The use of arsenobenzol derivatives, of mercurochrome and mercuric chloride, to mention only a few suggestions, has been advocated. But at present no satisfactory measures are available. The value of blood transfusion in any case of septicæmia is often very great. Experience suggests that it is desirable to test donors' cells directly against patients' serum, and not to rely on a "universal donor" in cases of septicæmia.

Finally, it may be stressed that at least three attempts should be made to procure a positive blood culture before septicæmia is excluded, and that this is particularly important in malignant endocarditis, where even under the best conditions by no means every case gives a positive result. Patients with chronic valvular lesions may become malingersers, and a succession of negative blood cultures with a high temperature in such patients suggests a careful watch over the taking of temperatures. On the

other hand, if blood cultures show, over a period of weeks, a growth of streptococci on repeated examination, particular attention should be paid to the heart as malignant endocarditis becomes, with passage of time, a more and more inevitable diagnosis.

R. J. V. PULVERTAFT, M.B., M.R.C.P.,
Pathologist to the Medical and Surgical Units,
St. Thomas's Hospital, Plimmer Research
Fellow in Pathology.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdr. R. W. Nesbitt is promoted to the rank of Surg. Comdr.

ROYAL NAVAL VOLUNTEER RESERVE.

Proby. Surg. Sub-Lt. J. E. L. Morris to be Surg. Sub-Lt.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. M. C. Beatty, having attained the age for compulsory retirement, is placed on retd. pay.

Temp. Lt.-Col. T. S. Blackwell to be Lt.-Col., vice Lt.-Col. W. J. Weston (decd.).

Temp. Lt.-Col. H. E. Priestley to be Lt.-Col., vice Lt.-Col. M. C. Beatty, retd. pay.

Maj. and Bt. Lt.-Col. C. M. Drew to be temp. Lt.-Col.

Maj. D. Pottinger retires, receiving a gratuity.

Maj. A. S. Littlejohns to be temp. Lt.-Col.

ARMY RESERVE OF OFFICERS.

The undermentioned, having reached the age limit of liability to recall, cease to belong to the Res. of Off.: Lt.-Col. P. C. Douglass and Maj. J. M. Cuthbert.

TERRITORIAL ARMY.

Maj. H. C. Sands retires on completion of tenure of comd. and retains his rank, with permission to wear the prescribed uniform.

W. F. Dorward (late Cadet, St. Andrews Univ. Contgt., Jun. Div., O.T.C.), E. Hutcheon, and E. J. Fitzgerald to be Lts.

INDIAN MEDICAL SERVICE.

Lt. G. G. M. Davis relinquishes his prob. appt. The undermentioned officers relinquish their temp. comms.: Capts. K. Ram and S. M. A. Khan.

COLONIAL MEDICAL SERVICES.

The following appointments have been made:—Dr. M. A. Minahan, Lady Medical Officer, Federated Malay States; Dr. W. T. M. Gilbert, Medical Officer, Nigeria; and Dr. T. S. Dalrymple, West African Medical Service.

PAYMENTS TO A MEDICAL STAFF.—In view of the increase in the number of patients since the establishment of a contributory scheme, the board of management of Warrington Infirmary decided that "it is only reasonable and fair that a proportion of the Contributory Fund should be paid over to the members of the medical staff," and the proportion was fixed at 10 per cent. In view, however, of the recent heavy expenditure upon additions and alterations the medical staff decided to return 25 per cent. of their total for 1929. The medical board report that the accommodation is still altogether inadequate.

HOSPITAL WORK IN THE DOMINIONS.—The Volkshospitaal, the nursing home of the Dutch Reformed Church at Cape Town, which has cost £54,000, has recently been formally opened. The ceremony was performed by Princess Alice, Countess of Athlone, who made a speech in Cape Dutch.

The *Alberta Medical Caravan* is about to begin its annual tour among the lonely farming communities of the Canadian West. The caravan consists of several specially equipped lorries, containing a complete hospital outfit, a dispensary, and a dental clinic, and the personnel is formed of two surgeons, two dentists, and four nurses. Each stopping place is notified in advance, the patients assemble there from the surrounding districts, and the caravan remains until all the patients have been disposed of. Last year more than 4000 examinations were made, 1408 operations were performed, and 4273 dental cases received attention.

Special Articles.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

THE JUBILEE CONGRESS.

THE Jubilee Congress of the Society took place on April 3rd, 4th, and 5th, at the house of the Royal Society of Medicine, under the presidency of Mr. LESLIE PATON.

The PRESIDENT presented the Nettlethip Medal to Miss Ida Mann for her investigations into the embryology of the eye, commenting on the excellence of her work in this field during the last ten years, and proceeded to deliver his Presidential Address on

SOME OF THE FACTORS CONTROLLING THE POSITION AND MOVEMENTS OF THE EYES.

He dealt mainly with the part played by the labyrinth and the proprioceptive impulses from the neck muscles in the control of the position and movements of the eyes. In man and animals with frontally placed eyes the retinal stimuli had a predominating place in the control of the position and movements of the eyes, and in such animals it was only possible to get good evidence of the importance of other lower dysergetic controls when the higher epicritic retinal controls were either removed or damped down. But the other factors were constantly present and in action, and when their functioning was interfered with important symptoms and signs were produced. The lower controls, as a rule, did not rise to the level of consciousness, and the cerebral cortex was not necessarily involved in the path of their arc. It was different with the retinal control, and, certainly in respect of the visual fibres, this was epicritic.

Mr. Paton described the unceasing control exercised on the position and movements of the eyes by the labyrinthine organs and by the reflexes from the movements of the head relative to the trunk. This control was definitely connected with the mechanism for the maintenance of general body equilibrium and of muscle tone, also with that of hearing; and this association produced a complexity of structure in the central nervous system which it was difficult to unravel. He sought to make two points in respect of labyrinthine control: (1) the constant nature of this control; (2) the fact that the basic nature of the end organ involved remained unchanged, structurally and functionally, throughout the animal kingdom; it was throughout a sensory organ, responding to variations in pressure. In all cases the activity of the sensory cells varied inversely with the pressure on them—i.e., the lower the pressure the greater the activity. The reflex connexion of the labyrinth with the eye muscles was obviously a very direct one, but it could also be shown that the effect produced was the result of the summing up of the effects of the two labyrinths, so that when one was destroyed the remaining one only produced half the effect. Mr. Paton proceeded to discuss the functions and connexions of the sacculus and the utricle, and showed that the maculae utriculi were linked up with the oblique muscles, and each utricle was linked up with all four obliques. It was clear, he said, that the utricle must link up with the superior and inferior recti. When a monkey was placed face downwards, both eyes looked upward; when it was placed on its back, both eyes looked down. He went on to speak of the semi-circular canals and the crista ampullae and their respective functions. He said that the nystagmus which resulted from destruction of a labyrinth lasted only a few days. The labyrinthine function in maintaining muscle tone and body equilibrium generally. A recognition of the complexity of the problem and of the number of gaps

in knowledge might stimulate the filling of these gaps. It was essential to have a better understanding of nystagmus and of some of the more obscure forms of ocular palsy and ocular disturbance.

Delegates from the United States, France, Holland, Spain, Italy, Norway, Sweden, Austria, and Belgium congratulated the Society on the attainment of its Jubilee, and presented an ivory presidential mallet, inscribed in enamel.

Mr. E. TREACHER COLLINS read a paper entitled *The Harderian Gland—Xerophthalmia; Vitamin A Deficiency; Keratomalacia.*

His deductions from the detailed evidence he brought forward were as follows: (1) the eyelids and para-ocular glands had been developed in animals living in an aerial environment to protect their eyes from foreign substances, and to prevent their corneal epithelium from undergoing keratinisation; (2) the lacrimal secretion acted mainly as an irrigating antibacterial fluid; (3) the mucous secretion of the Harderian gland preserved the corneal epithelium from keratinisation in the animals in which it was present; (4) the disappearance of the Harderian gland in primates was compensated for by an increased development of unicellular mucous glands in the retro tarsal folds and ocular conjunctiva; (5) in animals fed on a diet deficient in vitamin A the Harderian glands soon became atrophied and ceased to function, and in the absence of their secretion the epithelium of cornea and conjunctiva showed keratinisation; (6) in human beings on a deficient vitamin A diet the mucous secreting cells of the conjunctiva atrophied, and keratinisation followed; (7) keratinisation might affect the ducts of the lacrimal and meibomian glands, so that they became secondarily involved; (8) in the absence of its mucous secretion the surface tension of the conjunctiva became altered, so that the fatty secretion of the meibomian glands adhered to it, and this secretion formed an excellent medium for micro-organisms; the pathogenic ones excited an inflammatory reaction which, in the cornea, resulted in keratomalacia. Inability to see in a dim light after exposure to a bright light, a symptom frequently met with in association with xerophthalmia, had been produced in rats by a diet deficient in vitamin A, and was found to be accompanied by a marked delay in the regeneration of the visual purple. Further, xerophthalmia was frequently accompanied by pigmentation of the conjunctiva in dark-skinned races of mankind and animals. A 1 per cent. aqueous solution of mucin suitable for application to the eye could be prepared from the desiccated Harderian glands of sheep by the use of sodium hydroxide.

The afternoon sitting on April 3rd was devoted to a discussion on

Disorders of Secretion of the Endocrine Glands Associated with Eye Diseases.

Mr. J. H. FISHER, in opening the discussion, spoke of the complicated interacting mechanisms which controlled the carbohydrate metabolism of the body, and said that in spite of these complexities the ophthalmic surgeon seemed satisfied, when sugar was found in the urine, that he understood the aetiology of the case. In fact many endocrine glands might be playing a part in such a case, and there was great need for the biochemist and physician to come to the aid of the ophthalmologist. Myasthenia gravis had been described in association with hyperplasia of the thymus, with congestive enlargement of the parathyroids, and with exophthalmic goitre. That it might be due to some disturbance of endocrine glands was also suggested by the fact that in women the condition improved if pregnancy occurred. Thyroid extract had been used in its treatment. Osteomalacia attacked both sexes, and in the female was aggravated by pregnancy. Myxoedema was well controlled by organotherapy. This disease did not lead to lens changes; if cataract occurred after excision of the thyroid gland, it was probably due

to simultaneous removal of the parathyroids. The endocrine glands were factories, each turning out its special product which was essential to health. Mr. Fisher suggested that in cases of endocrine disorder the biochemists should investigate to the uttermost the constitution of the blood, from which alone the ductless glands drew their pabulum, and into which they poured their products.

Prof. H. MACLEAN discussed the connexion between glycosuria and eye changes.

Dr. W. CLARK SOUTER, Prof. E. C. DODDS, Mr. A. W. ORMOND, Mr. CHARLES GOULDEN, and Prof. MELLER (Vienna) also spoke.

Among many interesting papers and demonstrations was one by Mr. W. S. DUKE-ELDER, who gave by means of a series of slides some observations on the

Physiological Action of the Extra-Ocular Muscles.

He gave an account of experimental work he had been doing in order to show the effect of choline and acetyl-choline on the extrinsic muscles of the eye. The matter arose, he said, during a research upon the effect of various drugs upon the extra-ocular circulation, when peculiar reactions upon the intra-ocular pressure were registered with choline. The extrinsic muscles of the eye differed from muscles elsewhere in the body because their fibres were exceptionally fine and delicate, and it might be that their permeability was so great, owing to their fineness, that choline could diffuse in them. The reaction which took place with choline was traced to a contraction of the recti and obliques which was unaffected by atropine and was abolished by nicotine and curare. Mr. Duke-Elder pointed out that this reaction corresponded in every way with the phenomena described by Vulpian as occurring in denervated tongue muscle, and by Sherrington in denervated skeletal muscle, where pseudo-motor contraction of this order was obtained either by the stimulation of the sensory or vaso-dilator nerve-supply, or by the injection of choline. This peculiarity in the physiological action of the extrinsic muscles of the eye, that is, behaviour corresponding to that of denervated voluntary muscle elsewhere, was discussed by Mr. Duke-Elder in relation to the peculiarities of the sensory innervation of these muscles, and the curious anatomical features of the muscle-fibres themselves.

Dr. W. R. AYKROYD read a paper on

Functional Night-Blindness due to Vitamin Deficiency.

He said this recurrent difficulty in adapting the eyes to dim lights had been thought to be due to vitamin deficiency for several reasons. It occurred in association with a poor diet, was rapidly curable by giving cod-liver oil or mammalian or bird's liver, and was often noted in conjunction with external eye conditions similar to those produced experimentally in vitamin A-deficient animals. But the aetiology of the disease could not be regarded as established beyond question. He described the following observations made in Newfoundland and Labrador last summer. The diets of a series of cases of hemeralopia were found to be obviously deficient in vitamin A. In some patients the disease developed in less than a month after the patient had passed from a diet rich in vitamin A to one which was almost devoid of it. The conditions of the country, and the mode of life followed by the people made it difficult to obtain food containing vitamin A. All the cases were curable in 24 to 48 hours by one or two doses of cod-liver oil. Two fishermen had cured themselves by eating half a seagull's liver raw. Strong sunlight, however, played a part in the causation of this functional night-blindness; men exposed for long periods to sunshine in open boats were the chief sufferers. Women and children were rarely attacked by it. However, normal people did not develop the condition, whatever their exposure to the sun. In women, hemeralopia was usually associated with pregnancy, and tended to clear up spontaneously. Delay in the regeneration of the visual purple would account

for the observed clinical facts. Hippocrates was aware of the "liver cure" for night-blindness. For this particular functional form the term "nutritional dysskotopia" had been suggested.

Mr. FRANK JULER read a paper entitled

Some Cases of Damage to Descemet's Endothelium.

He quoted the words of Friedenwald in his recent book on the pathology of the eye: "The influence of Descemet's membrane on the nutrition of the cornea is entirely unknown, for the membrane and the lining endothelium combine to form a barrier against the passage of fluid and of substances in solution, from the anterior chamber into the cornea. When the endothelium is injured, the barrier becomes imperfect and oedema of the cornea results, which manifests itself (1) in the formation of blebs under the epithelium, (2) in a general milky haze of the cornea, (3) in the development of folds in Descemet's membrane." Mr. Juler's experience supported this statement. He described cases of (1) oedema of the cornea from a fragment of glass free in the anterior chamber, (2) corneal opacity resulting from irrigation of the anterior chamber in process of cataract extraction, (3) epithelial dystrophy of the cornea in two sisters. With regard to the second of these cases, the dangers of irrigation, apart from possible infection, were (1) loss of vitreous, and (2) the use of solutions of incorrect concentration or irritant action. These solutions must not be used too hot or under too great pressure. There was also (3) a danger of damaging the back of the cornea with the nozzle of the irrigator, the latter being especially to be avoided when there was recent damage to the endothelium.

THE GENIUS OF WILLIAM BOWMAN.

The Bowman Lecture was delivered by Sir ARTHUR KEITH, F.R.S., who began by relating an incident which gave an intimate view of Sir William Bowman's personality. James Syme, when Regius Professor of Clinical Surgery at Edinburgh, had publicly condemned the operation of iridectomy for the relief of acute glaucoma in 1857, and Bowman wrote him a personal letter stating that he found it the only certain and indispensable treatment for the condition. He did not himself rush into print, though eventually Syme sent the correspondence to the *British Medical Journal* in which his attack on the operation had appeared. Bowman made brilliant discoveries in anatomy in his youth, and in his full tide he did more than any other man in the domain of ophthalmology. Before he was 25 Bowman had advanced medicine by a series of notable discoveries; he had very rare gifts of mind, and he must have had some missionary quality which urged him on. It was an urgent desire for betterment which probably explained his distinction, yet only rarely could one obtain a glimpse of his motives. In his thirtieth year he delivered a lecture at Moorfields in which, after speaking of the pleasures of the earnest pursuit of knowledge, he referred to cases of blindness caused by inflammation of the cornea, and used these words: "These cases occur amongst the poor, a class to whom the eye is, if possible, even more valuable than to the rich, because without it they can hardly obtain their daily bread or enjoy the common comforts of existence." Later, in a lecture to students, he spoke of a strong yearning for the advancement of knowledge, and said his whole soul was overflowing with a sincere desire to know and to practise whatever was right. He shared fully that humanitarianism which animated so many great Victorians. The master and inspirer of Bowman, said Sir Arthur, was Prof. Robert Bentley Todd, his senior by only seven years, and Bowman shared with Todd the chair of anatomy and physiology, and was never tired of extolling his colleague's merits which seemed indeed to be of a high order. His paper, published in THE LANCET (1842, i., 560), on the appearances revealed by the microscope in a case of fatty degeneration of the liver must have been one of the earliest

—if not the first—in which the microscope was employed to elucidate finer pathological changes. Bowman himself was quite aware he was opening up a new field, and claimed that the condition he had drawn attention to “was an admirable example of the kind and degree of insight into pathological changes which the microscope was calculated to afford.” In the course of carrying out his microscopic survey of the glandular system of the body Bowman came to the kidney in or before 1841. He, in 1842, gave us at a single step our modern conception of the organisation of renal structures. For his paper on the structure of muscle he was elected Fellow of the Royal Society at the age of 25 (1841), and for his paper on the structure of the kidney he was given a Royal Medal. Bowman's account of the eye was the modern one—the eye as revealed by sections viewed through a compound microscope. Our conception of the cornea remained much as he left it; the ciliary muscle had no certain existence until he defined its relations, nature, and function, though he supposed that it served accommodation by altering the position, not the form, of the lens. He detected the circular and radial musculature of the iris, though it was left for later workers to amend his conception of the structural elements of that musculature. He saw the optic fibres circle on each side of the “yellow spot” yet dismissed the “spot” as of little importance in vision because it was not present in the eye of the dog, cat, rabbit, and bird—animals with perfect sight. He refused to regard the rods and cones (bulbs) as concerned in perception because they lay on the outer or “wrong” side of the retina. With a flash of insight he speaks of the eye as “a sheet of nervous matter brought towards the surface of the body to meet the appropriate stimulus,” and then, in another passage, stated that the relationship between the retina and the “sensorium” was a problem “too inscrutable for our limited powers.” Sir Arthur thought it could be said with truth that Bowman made a larger contribution to our knowledge of the anatomy of the eye than any other investigator. He certainly made mistakes, but when allowance was made for the primitive methods then at the disposal of microscopists, and the novelty and vastness of the field in which he laboured, the marvel was that he was so often right.

Sir Arthur touched on what he termed an enigma in Sir William Bowman's life. From his twenty-second to his twenty-sixth year investigations and discoveries followed each other regularly, and then his ardour for discovery, judged by results, seemed to have cooled, though he still added to the resources of medicine and surgery. Still, the last fifty years did not fulfil the promise of his earlier ones. An event of significance at this time was that in 1842 he was happily married, and the lecturer speculated on what might have happened had Bowman, in the full tide of his discoveries, been appointed surgeon to King's College Hospital in place of Sir William Fergusson. He concluded his lecture by drawing attention to the resemblances between Lister and Bowman. Both those great men proved in their first publications that they were not apprentices, but master workmen; both became Fellows of the Royal Society; they had much in common physically and their tastes harmonised; and both had a deeply rooted desire to help the poor and unfortunate. They were equally modest and unassuming. If in the turn which fate gave to Bowman's career general surgery could be said to have suffered, ophthalmic surgery certainly reaped rich reward.

Prof. VAN DER HOEVE read a paper on the

Eye and Amnion Bands.

He said these bands exercised a great influence on the development of the human being and they could cause great damage; they certainly were responsible for facial and other disfigurements, and might even cause amputation of limbs. In some cases such a band extended from the eye to the mouth, distorting both. He projected some pictures of patients so

affected and showed that much could be done to improve the appearance in some victims.

Mr. AFFLECK GREEVES read a paper on

X Ray Applications in Superficial Keratitis.

He showed that in cases of acne rosacea, a very painful condition with ulcers of the cornea and scarring, X rays produced a lessening of the pain and the photophobia. Often a single application of the rays brought great relief. The same measure gave good results in recurrent abrasions of the cornea, causing immediate and rapid healing. He was unable to record successes by this means in cases of Mooren's ulcer, though some of these patients reported diminution of pain. Neither did the rays cause marked improvement in bullous keratitis.

Mr. J. W. TUDOR THOMAS gave the results to date of a long investigation into the possibilities of

Transplantation of the Cornea.

He brought for exhibition four rabbits in which he had succeeded in producing clear corneal grafts. He said that transplantation of corneal tissue was first attempted 107 years ago, since which date many attempts had been made, but, so far, no really satisfactory operative procedure had been established. The sixth of a series of methods tried had provided good results. This consisted of the taking from the margin of the cornea of a graft of triangular or quadrilateral shape and uniting it to the cornea by cross-stitches, a wide iridectomy being performed so as to prevent the iris from adhering to the graft. Fourteen rabbits were operated upon in this way. In 13 of them the grafts became united. Two were quite transparent at three and four months respectively. Even better results were obtained when the grafts were circular. The various stages of the research were clearly shown by photographs of the rabbits exhibited on the screen. Mr. Tudor Thomas said that the grafts must be manipulated with great care and must not be grasped by forceps or other instruments. Olive oil should be used to lubricate any instrument which might come in contact with the graft, and the latter should be placed in sterile olive oil before placing it in the gap prepared for its reception. The margins of the graft should be cut in a shelving manner; it should be round, so that there were no corners to become detached and protrude. Partial detachment produced opacity, which usually affected the whole graft, as also did adhesion between the iris and the graft. Cross-stitching seemed to overcome most of the difficulties. He proposed to continue this work as it was far from complete. He intended to defer trying the method on a human patient until he had obtained more exact information from his experiments on rabbits.

In connexion with the Congress a reception was held at the Royal College of Surgeons, and Miss Mann gave a demonstration of pythons' eyes seen by the slit-lamp and of the ophthalmoscopic examination of various varieties of lizards and frogs at the gardens of the Zoological Society.

THE BANQUET.

The Jubilee Banquet was held on April 4th at the Hall of the Fishmongers' Company, with the President (Mr. LESLIE PATON) in the chair. Among the foreign guests present were:—Prof. Fritz Ask, Dr. Bailliar, Dr. Henri Coppez, Prof. Emile de Grösz, Dr. A. W. Mulock Houwer, Prof. J. van der Hoeve, Prof. Josef Meller, Dr. V. Morax, Dr. M. Marquez, Dr. E. Marx, Dr. René Onfray, Prof. Giuseppe Ovio, Dr. E. Pfleger, Prof. F. Terrien.

The President, in proposing the toast of the Society, said that of the 114 original members who held their first meeting in June, 1880, 111 survived. Two (Sir Thomas Barlow and Mr. J. B. Lawford) were present. Sir George Berry had been prevented from attending by urgent political business. Among the first vice-presidents had been George Critchett and that great clinical observer, Jonathan Hutchinson.

Mr. Paton advised any young man who thought he had discovered a new clinical fact to make perfectly sure that Jonathan Hutchinson had not already described it. He felt that we were on the verge of great advances in our knowledge of the structure of the body; that we were indeed standing on the boundary of a new and undiscovered country, some of the prominent features of which were beginning to show up through the mists of morning.

Sir THOMAS BARLOW, responding to the toast, described the origin of the society from a group of young men who had met in the house surgeon's room at Moorfields to discuss subjects which interested them. The first secretary, Edward Nettleship, had been clinical assistant to Jonathan Hutchinson. Nettleship had gathered up the experience of Moorfields and its great traditions; he had had the most comprehensive knowledge of the pathology of the eye. Another early member was Warren Tay, a modest man who had never achieved the reputation he deserved. Other original members were Stephen McKenzie, Brailey of Guy's Hospital, Morton, George Berry, and Marcus Gunn. Two great men not among the original members had had an abiding influence on the society—Jonathan Hutchinson and Hughlings Jackson. After the club had met for a year it had seemed time to enlarge its scope, and a circular letter had been sent round. Seniors who were not members had given generous support, among them William Bowman and William Gowers. The club and society had made a common meeting ground for surgeons, physicians, and pathologists, and that common ground had been one of the causes of its success. The history of the Ophthalmological Society was a lesson to the whole profession on the spirit in which specialties should be considered.

The health of the Bowman lecturer was proposed by Sir JOHN PARSONS. Sir Arthur Keith, he said, had two methods of attack when he found himself confronted with a new specimen of *Homo sapiens*. His synthetic method had made him the champion jigsaw puzzler of the world, and he had recently got into trouble with the theologians because he had been unable by his analytic method to find the soul. Descriptive anatomy was the valley of dry bones spoken of by Ezekiel, the prophet, but the prophet had had a vision, and Sir Arthur Keith must have imbibed that spirit, for no other anatomist was so good at making dead bones live.

Sir ARTHUR KEITH, in reply, said that the society had given him that afternoon the finest of all subjects on which to speak—a great man whose greatness had not been fully realised. The history of William Bowman had much to do with the success of the Ophthalmological Society. England was the recognised home of three great schools—the physiological, the neurological, and the ophthalmological—and between the last two there was something akin. Ophthalmology was not narrow; it dealt with the whole body. Men working at the retina were working at the brain, and it was possible to obtain more intimate insight into the great systems of the human body through the eye than through any other part.

The toast of "The Guests" was proposed by Mr. J. H. FISHER.

Prof. VAN DER HOEVE, in reply, conveyed greetings and thanks from the foreign guests, and on their behalf presented to the chairman an ivory presidential hammer. Bowman would, he felt, have approved of this gathering, for he had been one of the most international of scientists, visiting foreign centres and entertaining foreign scientists at his home. The society had kept to the high standard of scientific endeavour bequeathed to it by its first president.

Sir JOHN BLAND-SUTTON, who also replied, said that he had attended the second meeting of the society in December, 1880, at the invitation of Mr. Critchett, a man who had so impressed him as a student that he had nearly become an ophthalmic surgeon. Critchett had been ambidextrous, and would

take out the lens of the right eye with the right hand and the lens of the left eye with the left hand at a single operation, and while he manipulated the cornea he had held his cataract knife in his mouth. In those days most ophthalmological work had been done by general surgeons, but the invention of the ophthalmoscope had changed all that. The ophthalmoscope was the prince of clinical instruments and ophthalmology the most justifiable of specialties.

Mr. TREACHER COLLINS proposed the health of the Chairman and Mr. LESLIE PATON briefly replied.

THE DISTRIBUTION OF LEAD INSIDE AND OUTSIDE THE BODY.

QUANTITATIVE INVESTIGATIONS INTO THE PRESENCE OF LEAD IN VARIOUS SUBSTANCES, AND ON ITS ABSORPTION AND EXCRETION.

IN the course of experimental work conducted by the Departmental Committee on Ethyl Petrol certain investigations were made, the results of which are of general interest independently of the purpose for which they were organised. They are concerned with the presence of lead in the urine, in dust of streets or garages, the amount of lead retained by the lungs, and so forth, and were performed under the direction of Mr. A. G. Francis, F.I.C.

Lead in urine.—Minute quantities of lead were found to be present in the urine of almost every subject examined (average 0.040 mg. per litre). Persons living in towns excrete more than persons living in rural districts, and persons exposed to a definite lead hazard excrete comparatively much larger quantities. These findings are in conformity with the observations of the United States investigators. The detection and measurement of minute quantities of lead in urine have been made possible by the greater refinement in analytical methods which has been achieved in recent years.

Lead in the settled dust of the streets.—This investigation was undertaken to ascertain to what extent the general population is liable to take in small daily amounts of lead. The results of the experiments show that the settled dust almost everywhere contains small quantities of lead (from nil to 3.3 per cent.). It is calculated that dwellers in London inhale, on the average, nearly one-tenth of a milligramme of lead in a day. It is therefore not surprising to find that lead is absorbed into the system as shown by its presence in the urine of normal persons.

Lead in the settled dust of garages.—In London small quantities of lead are found similar to those found in the settled dust of the streets, but far less than those in the dust of factories where lead is used.

Lead in lubricating oil.—Oil from the crank case of cars that have not used ethyl petrol contains no volatile lead, and only traces of non-volatile lead, the maximum proportion of non-volatile lead found being only 0.01 per cent., and this non-volatile lead is present in the "carbon," that is, it is insoluble in the oil itself.

A very slight quantity of lead was found in samples of lubricating oils from cars run on ethyl petrol, but it was calculated that the proportion of volatile lead remaining on the hands of a mechanic at any given time would not be likely to exceed 0.6 mg.

Proportion of lead retained in the lungs.—The conclusions reached were that (1) Dilution of exhaust gas containing lead compounds with air is rapid. (2) The likelihood of users of the streets inhaling a dangerous quantity of lead when "puffs" of lead compounds are blown out from the exhaust pipes of motor vehicles during the acceleration of their engines is remote. (3) The daily dose of lead likely to be retained in the lungs of vehicular drivers and

other users of the streets under traffic conditions more severe than obtain in the streets at the present time is far below the quantity stated by Legge to be the minimum quantity of lead which, inhaled as dust or fume, may in the course of years set up chronic plumbism.

The Absorption and Excretion of Lead by Normal Rabbits in Captivity.

Certain control experiments carried out by Prof. W. E. Dixon, F.R.S., on the absorption of lead yielded interesting results. Five rabbits were clipped for a space of about two inches square on either side of the back adjoining the spine. In five others the same area of hair was removed by a depilatory.

Two liquids were used for application to the skin. One of these was prepared from ordinary petrol. The petrol was redistilled, the last 5 per cent. left in the still being kept for use. The second liquid was used for purposes of comparison and consisted of petroleum ether which had been redistilled.

Five rabbits each received 15 drops of redistilled petrol on the shaved parts daily. The other five rabbits were treated in the same way except that petroleum ether was used. Each rabbit received in all 18·4 c.cm. applied to the skin.

The animals of this series received no lead except by contamination of the food or through dust, and neither of the volatile liquids which were applied daily contained lead. During the two months which the experiment occupied, samples of urine from each group were sent on three occasions for analysis in lead-free bottles and at the conclusion of the experiment, when the animals were killed, samples of the liver, brain, and kidney were also sent to the Committee's Laboratory.

The treatment had no effect on health or appetite, but one remarkable feature in the experiments was the fact that the urine from the petroleum ether rabbits was about three times as great as that from the petrol rabbits. This feature became less marked after the first few weeks, though later it again became pronounced. The exact figures of four typical rabbits were as follows:—

In the first 11 days two rabbits treated with redistilled petroleum ether passed on an average 210 c.cm. of urine a day. Two similar rabbits treated with the last 5 per cent. petrol passed on an average 55 c.cm. of urine per day; that is, in 14 days these last rabbits passed 1428 c.cm. of urine, whilst the petroleum ether rabbits passed 5450 c.cm. of urine. During the next seven days, whilst the petrol rabbits passed 2250 c.cm. of urine the petroleum ether rabbits passed 2620 c.cm. of urine. After a break of three weeks, during a period of ten days, the petrol rabbits only passed 1000 c.cm. of urine, whilst the petroleum ether rabbits passed 2240 c.cm. of urine.

The observations showed that normal animals in captivity absorb and excrete traces of lead. The lead is taken by the mouth with food or is absorbed as dust from the nasal mucous membrane. Most of that taken by the mouth we know is converted into the insoluble sulphide and passed out by the faeces unchanged. A very small amount of this is absorbed and a variable percentage, which is believed to be constant, is excreted by the urine, the rest being again excreted by the bowel. Some lead is retained, mainly in the bones, liver, and kidney. In acute poisoning as much as 95 per cent. of the retained lead has been found in the bones, but in chronic poisoning the bones contain very little.

In the normal control rabbits only about 3·7 mg. of lead was excreted by four rabbits in 54 days. No great difference occurred between the excretion in the two groups, though the larger amount of urine excreted in the petroleum ether rabbits carried with it a trace more lead. The livers, brain, and kidneys of these control animals also showed no appreciable amount of lead.

Experiments using ethyl petrol applications showed that the excretion of the lead under these conditions

is mainly by the bowels and, further, that in the amounts used the rate of excretion kept pace, or nearly so, with the rate of absorption. The experiments proved that the daily application to the skin of rabbits of 0·27 c.cm. of 2 per cent. lead ethyl dissolved in distilled petrol is without ill-effect of any kind up to 130 days, in spite of the fact that the skin was specially prepared to facilitate absorption. To obtain a comparable experiment with ethyl petrol, on the assumption that ethyl petrol contains 1 in 1300 by volume of lead tetra-ethyl, 7 c.cm. would be required daily.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

The San Francisco Cancer Sensation.

Dr. Walter B. Coffey and Dr. John D. Humber, of San Francisco, observed that the injection of an extract of the suprarenal cortex of the sheep causes softening and liquefaction of carcinomatous tissue. The observation came as the result of treatment of patients with hypertension who happened to have carcinoma as well. When these experimental observations were announced to the Pacific Coast Surgical Association, reporters of the Hearst press obtained word of them and whole pages were devoted to the great discovery and to the generous instincts of the press for the benefit of humanity as contrasted with the conservative reticence of the medical profession. Telegrams and letters began to pour in to the offices of every physician and association that might be suspected of esoteric knowledge of the "cure." The doctors were summoned to give evidence before a committee of the Senate in Washington what time cancer sufferers began to trek across the continent in the opposite direction. To calm the excited multitude it has been necessary to appoint a strong committee of investigation including Surgeon-General Cummings, Dr. Charles Mayo, Dr. Morris Fishbein, Dr. Francis Carter Wood, Dr. Joseph Colt Bloodgood, and others. The expenses of this committee are to be borne by the Chemical Foundation.

Osteopath as Health Officer.

A year ago the city council of Ellensburg in the State of Washington appointed an osteopath as city health officer. Acting under advice from the State Board of Health the incumbent physician refused to vacate office on the ground that the new appointee was not a "legally qualified physician." This conclusion of the State Board of Health was sustained by the first court but their judgment has now been reversed by the supreme court of Washington. The supreme court holds that the term physician has of late years been broadened to include the osteopath. The possibility of a health officer refusing to carry out the regulations of the Board of Health in regard to vaccination and the administration of antitoxin is one that the court does not seem to have had under consideration. An effort will be made to have the whole question reviewed. In the meantime the idea is slowly but steadily gaining ground that it is well to appoint to public health positions men who have diplomas in public health.

Secret Remedies on the Air.

The advertising of secret remedies in the more respectable journals is becoming less common. Proprietors of such wares have, however, discovered a profitable field of advertisement in the broadcasting stations with which this country is richly endowed. The first definite steps to correct this abuse have been taken recently in New York City, where the Public Health Commissioner, Dr. Shirley W. Wynne, has held three public hearings on the subject. Some 40 radio broadcasters decided that Dr. Wynne should select a committee of public

health officials and devise a plan by which broadcasters might receive explicit information quickly in programmes of a medical nature. Another committee of business associations is to report amendments to the code of ethics of the National Association of Broadcasters. Opposition takes the standpoint that any remedy or device which is not illegal has a right to advertisement; the larger broadcasting companies, however, agree that no remedy should be so advertised if it rests under any kind of suspicion. The Welfare Committee of the New Jersey State Medical Association has also taken some steps in opposition to radio quackery. The secretary of the Board of Medical Examiners has been kept informed of radio speeches that amounted to the practice of medicine and one man has already been convicted on a charge of practising medicine without a licence.

First-aid in Industry.

A method of organising first-aid and accident prevention work in industry has been worked out by Dr. D. L. Lynch, medical director of the New England Telephone and Telegraph Company. At first he attempted to spread a knowledge of first-aid by medical instructors, but he has found it more successful to train picked representatives from among the employees and to let them train their fellow workmen. These lay instructors are selected for qualities of leadership and once they have grasped the principles themselves are especially efficient in explaining them to other workers who in their turn are more willing to ask questions from a fellow employee. These trained men help to popularise modern methods of accident prevention and to bring for early treatment many cases that would suffer neglect but for a confidential intermediary. Many of the medical societies throughout the country are now reconsidering the official attitude of condemnation towards medical men employed by "contract" with industrial concerns. If one may judge from editorial expression in some of the State medical journals the profession is about ready to endorse this form of medical practice.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Road Accidents and Voluntary Hospitals.

The burden put upon the voluntary hospitals by road accidents is steadily increasing here as in England. At the recent annual meeting of the Monkstown Hospital the chairman, Dr. W. M. Wright, stated that 90 cases of motor accidents had been treated in the hospital during the year, costing double the amount expended in respect of all other accidents. Many of those injured are well-to-do people, who make little or no contribution to the hospital funds. And, again, for a high proportion of the road accidents someone is made amenable at law, and therefore liable for damages. In the great majority of such cases the hospital gets nothing. The board of Monkstown Hospital passed a resolution asking that a law should be passed to render insurance against third party risks compulsory on all motor-drivers, and making the cost to voluntary hospitals in case of motor accidents a first charge on the insurance money.

The Royal Victoria Hospital, Belfast.

The senior surgeon to this hospital, Mr. A. B. Mitchell, has retired from active duties in the wards to the great regret of his colleagues. He has been elected consulting surgeon, and his administrative abilities will be retained in its service in his capacity of vice-chairman of the board of management. He is succeeded in the wards by Mr. P. T. Crymble, surgeon to out-patients. Mr. G. R. B. Purce has been elected assistant surgeon.

The late Dr. Charles Dundee.

Dr. Charles Dundee, who died unexpectedly at Ballycarry on April 3rd after a brief illness, belonged to a medical family well known in County Antrim. He was the son of Dr. C. Dundee, of Ballycarry, the brother of Dr. W. B. H. Dundee, of Ballynure. He was educated at the Royal Academical Institution, Belfast, and Edinburgh University, where he qualified in 1913, taking the D.P.H. a year later. During the war he served with the Ulster division, and was gravely wounded, losing his left arm. He received the Military Cross for great gallantry under fire. After demobilisation Dr. Dundee was appointed assistant tuberculosis officer for Co. Antrim. He had a charming manner, and was as popular among practitioners as he was in the public health service. Moreover, he took an active interest in the farming community amid which he lived.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

A Fatal Accident with Diathermy Apparatus.

A FEW weeks ago public attention was aroused by an accident which caused the death of a well-known physician specialising in electrotherapy. The physician was seen by a servant when he was standing in front of the apparatus, the lid of which was open, with both his hands inside the machine making some adjustment. Suddenly she saw a bunch of sparks darting from the apparatus, heard a scream, and saw her master fall to the floor. She ran to him and screamed for help, but some time elapsed before anyone came to the scene of the accident. Even when medical help was procured, it was first thought that the physician, who had suffered from heart trouble, had had an attack of angina pectoris; thus valuable time was lost before artificial respiration was instituted. When the real cause of the accident became evident it was too late. Subsequent investigation showed that the physician had been the victim of his own insufficient precautions. He had a pair of indiarubber shoes on his feet and indiarubber gloves on his hands, but these latter were not in perfect condition. He had evidently switched on the current whilst working on the apparatus, in the attempt to find the origin of a fault in the machine, believing that he had insulated himself. This accident has caused alarm among patients who are unwilling to undergo medical diathermic treatment, though it has been publicly stated that diathermy is absolutely free from danger to the patient. The unfortunate physician met his death only because he unscrewed the lid of the machine and meddled with the fittings without turning off the current of 220 volts which passed through his body. This is the first instance on record of death caused through the medical diathermy set.

Treatment of Detachment of the Retina by Ignipuncture (Gonin's Method).

At a recent meeting of the Vienna Medical Society Prof. Lindner demonstrated nine patients on whom he had successfully performed the so-called Gonin's method of operation for detachment of retina. The method consists in cauterising the torn edge by means of an electric cautery. Prof. Gonin uses the cautery for four seconds, whilst Prof. Lindner leaves it in situ for from 8-15 seconds. Dr. Guist, Prof. Lindner's first assistant, has constructed an apparatus which works like a perimeter, with which he is able to locate the exact point to be cauterised. Hitherto the difficulty of locating this spot has been a great disadvantage of the method, so that Guist's appliance is a distinct and important advance. Prof. Lindner claimed that in detachment of less than four weeks'

standing over 50 per cent. of permanent cures could be obtained by the galvanocautery. Older cases of detachment, however, rarely gave very satisfactory results. This "new" method, although now practised by its author for several years, has not many adherents outside of Switzerland, where Gonin works, and Lindner's clinic is probably the only place in Austria where this operation is being systematically tried out.

Legal Protection of the Title "Dentist."

The Board of Education has recently issued two orders which are the result of protracted negotiations between the dental section of the Wirtschaftliche Organisation (Union of Practitioners) of Austria and the Government, concerning the right of a medical man to style himself "dentist." This is the first instance in this country of legal protection of the title of a specialist in any one branch of medicine, and it is expected that it will soon be followed by a general declaration of what training a specialist must have in order to claim this title. According to the new regulations a dentist must first of all pass all the examinations necessary for qualification as a doctor in this country; then he must work for at least two years at a dental clinic, and, moreover, pass an examination showing his proficiency in anatomy, pathology, and surgery of the teeth, and mechanical dentistry. Furthermore, he must practise in dental work exclusively, and may not combine it with any other branch of medicine. Of course, any medical man is entitled to do dental work as a part of his other medical work, but he is not to call himself dentist, but remains a general practitioner.

Detection of Diseased Arteries by Uroselectan.

At the last meeting of the Gesellschaft der Aerzte Dr. Sgalitzer, from Prof. Eiselsberg's clinic, together with Dr. Kollert, showed a new method for the examination of arteries by means of X rays. The artery is laid bare under local anaesthesia, and 10-15 c.cm. of uroselectan—an organic compound of iodine, in which the iodine is firmly attached to the organic molecule, is injected into the artery with a fine needle. There is no danger of iodism, as has been amply demonstrated by using this drug in pyelography, and no free iodine appears in the urine. As the injection into the artery is sometimes painful, it is desirable to give a few whiffs of ethyl chlorido to induce light general anaesthesia. If the arteries are believed to be diseased, the strictest aseptic conditions must be observed. The injection is in the first place done for diagnostic purposes; hitherto ten patients have been so treated. In some cases (one a case beginning gangrene of the big toe) a remarkable improvement has been the unexpected result. The authors, who have been assisted by a surgeon, Dr. Demel, have hitherto tried this method only on the arteries of the extremities, and have demonstrated the presence of emboli, thrombi, endarteritis, and arterio-sclerotic changes of spastic conditions. By combining the uroselectan injection with vaso-dilating substances, it is possible to differentiate spastic from organic stenosis of the vessels. If deposits of lime are visible in the arterial wall, before injection, the evidence is in favour of organic disease. If spastic conditions are found, treatment with yohimbine (1-5 mg. per day) is said to give good results, especially in ischaemic conditions like nicotine-intoxication or syphilitic endarteritis. Investigations of the capillaries under the finger-nail margin after uroselectan injections gave very interesting results. They show that these injections distinctly influence the circulation in the capillary system in the direction of increased pressure and flow of the blood stream. The indications for the new method are as yet not established. But in aneurysm of the peripheral arteries and in various pathological conditions of the venous system it should give useful results. So far it has served to localise exactly the site of an embolus, and the site of election for amputation in cases of peripheral occlusion of an artery.

CONFERENCE ON BIRTH CONTROL.

THE GIVING OF INFORMATION BY PUBLIC HEALTH AUTHORITIES.

A CONFERENCE organised by the National Union of Societies for Equal Citizenship, the Society for the Provision of Birth Control Clinics, the Women's National Liberal Federation, and the Workers' Birth Control Group, to discuss the giving of information on birth control by public health authorities, was held at the Central Hall, Westminster, on April 4th.

Birth Control and the Population Problem.

Dr. KILLICK MILLARD (M.O.H., Leicester), who presided at the morning session, said he was impressed by the profound change in the public attitude to this question in the last few years. The principal object of this conference was to emphasise the demand to the Ministry of Health to remove the embargo against the giving of information on birth control at municipal antenatal clinics. If birth control was to be justified as a national policy it must be based on something broader than individual hardship—that is, on the assurance that there were sound national and international grounds for believing that unlimited increase of population was not desirable.

Mr. HAROLD WRIGHT gave an able exposition of the Malthusian doctrine, and explained that the demand for increasing population might be met either by a falling death-rate or a rising birth-rate, but there was all the difference in the world between the two in terms of human well-being and happiness. Mr. Wright regarded birth control as an unmixed good, both from the point of view of the individual and of the race as a whole.

Birth Control and Maternal Health.

The CHAIRMAN referred to a statement made by Dr. Vernon Davies in the House of Commons recently, that competent gynaecological and obstetric surgeons were opposed to birth control, and quoted figures of answers received by him to a questionnaire on this subject to prove that the opposite was the case.

Mr. HAROLD CHAPPLE, F.R.C.S., based his arguments on three fundamental questions: (1) Were there any medical grounds on which married people needed information about birth control? (2) Had they a right to it? (3) Were the public health authorities the people who should supply it? He believed the answer to all three questions to be in the affirmative. The out-patient department of any hospital would supply ample evidence on the first point. A woman with several children, suffering from an uncompensated heart and again becoming pregnant, a tuberculous patient, or a woman with kidney disease, furnished three gross and obvious examples of cases which existed in thousands. People who objected to birth control asked why it should not be possible to exert such self-control that these catastrophes never occurred. Mr. Chapple thought that people who put that forward as a serious suggestion must have either a very limited or a very fortunate experience. For those obliged to share a bed it would impose a physical strain too great to be borne. In some persons the sex urge was comparatively slight, in others an almost overwhelming force. Much clinical experience led him to the conclusion that there was no such time as a "safe" period. The underlying principle of birth control was in line with the medical view of prophylaxis. Modern devices might occasionally produce a little local soreness, but Mr. Chapple had never seen a case in which real harm had been done. These methods were available to the well-to-do, why should they be withheld from people whose one source of information was that of clinics? This kind of teaching could not be given in the out-patient departments of hospitals. Knowledge need not be thrust on people who did not want it, those who did want it had a right to it. He urged local authorities to help

in bringing about what he believed would be a great blessing.

Dr. HELENA WRIGHT spoke from her personal experience at a birth control clinic on the effects of sound birth control knowledge and practice on maternal health. There were good and bad methods of birth control, and a good method must be reliable, harmless to the health of mother, father, and children, easy to learn and apply, and cheap. The question was not one touching the poor alone; there came a time in every family when the mother decided that she had enough children. If she was denied a knowledge of birth control four alternatives were open to her: (1) she could continue to live in her present state of anxiety, resulting in strained relationships between her and her husband and children; (2) the father and mother could decide to live henceforward merely as friends, but this would also submit the partners to an unreasonable and unnatural strain; (3) the couple could devise home-made methods of birth control, as was frequently done. The commonest procedure was what women described as "being careful," which was quite unreliable and a complete denial of the physical side of married life; (4) the fourth alternative was the sinister business of abortion. If an ideal method of birth control could be discovered there ought never to be another deliberately induced abortion. Another result, though an indirect one, would be that in properly conducted hospitals where knowledge could be obtained women might come for regular examination, with the result that all diseases of the pelvis could be prevented or attacked at an early stage.

Miss STELLA BROWN put in a plea, in which she was supported by the Hon. Mrs. BERTRAND RUSSELL, that abortion, properly conducted in hospital in the early stages of pregnancy, should be legalised in this country as it had been in Norway.

Dr. HALLIDAY SUTHERLAND drew attention to the fact that nobody had suggested reducing the size of families by the improvement of living conditions; the whole thing depended on environment. The effect of birth control on maternal mortality should not be overlooked: Bermondsey, with a high birth-rate, had a maternal mortality-rate of 2 per 1000, whereas Westminster, with a low birth-rate, had a maternal mortality-rate of 12 per 1000. Danger to the mother was greatest in the first confinement, the risk becoming progressively less until after the fourth, and the lowest death-rate was among the youngest group of mothers. Undue delay of the first confinement and too prolonged spacing of the family increased the risk of death in childbirth.

Dr. F. A. BELAM (M.O.H., Guildford) said there was much confusion of thought and ignorance about the difference between birth control and abortion, and it was of great importance that information should be properly given and not picked up haphazard.

Mrs. EVA HUBBACK, who took the chair at the afternoon session of the conference, said that discussion of the attitude of the public health authorities was peculiarly opportune at the present time, since under the new Local Government Act the local authorities would have more power to undertake any work they chose. Under the Maternity and Child Welfare Act it was the duty of the public health authorities to give advice to pregnant mothers, and advice on birth control should be an extension of this power. The session would be confined to a discussion of methods of conveying the necessary information to married women.

Dr. MATTLAND RADFORD (Shoreditch) said that public health measures were continually defeated by ignorance in the homes. It was impossible for a poor mother of 10 or 15 to preserve a suitable environment for growing children, or even to provide accommodation for them. Contraceptions were much more used in the middle than in the labouring class. He recommended "of management." He mentioned Mr. P. T. Crymble and Mr. G. R. B. Purce has been

women, at special centres to which all women requiring this advice should be referred. Men attending tuberculosis and venereal centres should also receive instruction in contraception; (3) to women with limited incomes, and growing families, to prevent overcrowding. Birth control centres should be under the charge of medical women supported by trained nursing staffs. The information should not be combined with advice at infant welfare or antenatal clinics, since these subjects were wide enough in themselves. The public health authorities should coöperate with existing voluntary centres, and later establish centres of their own. At Shoreditch a women's hospital was to be opened at which this advice would be given in addition to medical and surgical treatment of disease.

Mrs. POWELL (Reigate) described the origin of a birth control clinic in connexion with the maternity and child welfare work in her area. The town council had raised no objections to the scheme.

Mrs. D. THURTELL thought the chairman unduly optimistic about the powers of the local authorities under the new Act, but said that it was important to involve them in the work as much as possible, so that the movement would have become a powerful one should the Ministry of Health intervene later. As to methods, country districts might be supplied by travelling clinics; welfare centres and sunlight clinics might permit the use of their buildings on vacant days. Mothers would be more ready to attend a familiar place where the personnel was known to them.

Mrs. H. J. LASKI said that in 1925 the Ministry of Health had issued a circular to maternity and child welfare centres saying that women who appeared to require advice on contraception on medical grounds should be referred to a private practitioner, to a hospital, or to a birth control clinic. In practice it was found that these patients were not cordially received at hospitals, that the clinics were too few, and that the medical practitioners recommended by the Ministry could ill spare the time to give detailed advice to women who, moreover, could seldom afford a fee. The expense of starting centres in the buildings at welfare clinics should not be great. Birth control should, of course, be taught on days other than those devoted to welfare work. Proposals for new centres should certainly be put before local authorities, but the work was urgent, and should be undertaken at once, using existing means.

Mrs. SYDNEY FRANKENBURG thought that centres should be run in association with a welfare clinic or hospital. She gave practical details of a centre which was running satisfactorily. A small charge was made to the women.

Among other speakers Dr. NORMAN HAIRE said that though no fool-proof contraceptive had so far been available, constant experiment was leading to improvements. All methods required care and attention to be successful. The question of expense was subsequently discussed, and the possible increase in rates as a result of establishing centres was mentioned.

In replying, Dr. RADFORD said that spacing of children should be part of public health work for economic as well as hygienic reasons. A spread of opinion in favour of birth control would lead to its inclusion in the public health scheme.

Resolution.

In conclusion Mrs. HUBBACK moved the following resolution:—

"That this Conference calls upon the Minister of Health and Public Health Authorities to recognise the desirability of making available medical information on methods of birth control to married people who need it on medical grounds or who ask for it."

... point to be cauterised. ... difficulty of locating this spot has been ... of the method, so that Guistied, and the ... advance. ... of less

"Audi alteram partem."

ATHLETICS IN SCHOOLS.

To the Editor of THE LANCET.

SIR,—With deference to Dr. Cove-Smith it seems difficult to agree with some of his views on rowing. When rowing is properly taught the muscles of the trunk and limbs are brought into play with the work apportioned so as to avoid certain of these muscles becoming "overworked at the expense of others." The heaviest strain is put on the back and thighs, regions which are best provided to meet it. The hands and arms deal with the finish of the stroke, the feather and the clearing of the hands quickly over the knees before sliding forward for the next stroke. The last of these three phases is carried out by the action of the triceps, and, although it comes into action and development more than the biceps or other muscles of the upper arm, it scarcely can be said to be "overworked," or even "overworked at the expense of the other muscles."

Dr. Cove-Smith states "the return flow of blood from the lower half of the body is not adequately provided for." I must confess I am too dense to discover his meaning here. With feet on the stretcher they are merely a few inches below the level of the hips. In the swing back they are only a very little more than this below the level of the heart. A further assistance to emptying the veins is brought about in the constant muscular actions from abdomen to feet in the bendings at hips, knees, and ankles. Has anyone ever heard of varicose veins, or unduly dilated veins of the legs or abdomen occurring as a result of rowing? Varicose veins of the legs are occasionally seen, but the condition is neither due to rowing, nor affected by it.

One can agree with Dr. Cove-Smith when he says that provided the individual is of "sound constitution" he will derive benefit from rowing, but otherwise he may do himself more harm than good." There is no great need, too, for uneasiness on this point. If the fact of being unsound has not been discovered before taking up rowing, it will very quickly be seen, once he attempts to learn. His coach will notice it and the beginner will be conscious of it himself before he meets with the amount of strain that would be injurious. Rowing is only for those that are sound. It does not seem necessary, though, to weigh the question of physique with as much importance as that of soundness. Rowing is a fine developer of physique and, provided a youth is organically sound, its fascination need not be confined to those who are the pick in this respect.

What is the "distinct medical problem at the present" in the middle-aged man, formerly a rowing man, that is referred to? Can it be a tendency to obesity? This does not seem to occur more frequently from rowing than from some of the other forms of athletics. It should be remembered, too, that rowing has a good percentage of what can be looked on as the lefty type. It was only on Saturday last in the head-of-river race over the Mordlake to Putney stretch of 4½ miles an eight in the first division was stroked by an oarsman of 60! And covered the distance in 20 minutes, in or about. An outstanding oarsman, it is granted. In the same race there was a crew in which none of the members were under 40! What is the "distinct medical problem" to be put down as? And with regard to what are referred to as "the faulty methods of training of the last century," these methods evidently did not injure the stroke of 60 years of age. The crew of "40 and over" would escape them as very likely each member would have been too young to be in training then.

Dr. Cove-Smith's views on Rugby football for boys are naturally valuable, and personally I give due

weight to his opinion that the game should be under taboo before public school age.

I am, Sir, yours faithfully,

J. ARMSTRONG HARTLEY.

INTRAVENOUS INJECTION OF ETHYL ALCOHOL.

To the Editor of THE LANCET.

SIR,—In your issue of June 15th, 1929 (p. 1247). Dr. J. D. Constantin (Greenwich) described a method of general anaesthesia by the intravenous injection of ethyl alcohol advocated by Dr. M. G. Marin, of Mexico City. Dr. Constantin writes: "The use of ethyl alcohol intravenously had not, as far as I know, been reported until Dr. Marin's experiments became known. (Thesis presented to the National University of Mexico, 1929.)" I should like to call his attention to the fact that in 1927-28 I published in the *Zeitschrift für Krebsforschung* and in the Polish medical journal *Czasopismo Lekarskie* a method of cancer treatment consisting in intravenous infusion of 33.3 per cent. ethyl alcohol (in Ringer's or physiological salt solution). To this method I was brought by theoretical reasoning, and I was able by many animal experiments to prove that intravenous infusion of great quantities of ethyl alcohol, even in absolute form, can be given without danger.

I am, Sir, yours faithfully,

Warsaw, March 28th, 1930.

Dr. D. THURSZ.

IRRADIATED ERGOSTEROOLS.

To the Editor of THE LANCET.

SIR,—Keen commercial competition combined with the modern craze for an all-vitamin factor in dietetics will soon flood the market with a series of proprietary food products of questionable quality, specially milk products guaranteed to contain a fair proportion of vitamin D. Experimental evidence is far from convincing, and remarkably divergent views are expressed regarding the general use as a therapeutic or prophylactic measure of a concentrated vitamin D factor in irradiated milk. The more one reads of vitamin D, the more is one convinced of the limited knowledge we still have of this accessory food substance. It will be many years before vitamin D problems can be recognised on established basis. It is premature, therefore, to employ a principle of doubtful utility to improve a standard natural product such as milk. To alter the properties of fresh milk by artificial light radiations or by the addition of a foreign product and to recommend this for general use is from all points of view against natural laws—the same laws which control vitamin active principles. For, have we not been told ever since Funk discovered "vitamine" that all similar unidentified factors or accessory food substances are most likely to be present in natural food? Moreover, if we are at all to accept Dr. K. Coward's recent alarming report that fresh milk, the only natural food for infants taken during all seasons, contains hardly any vitamin D, then the logic of irradiating milk to concentrate the same active principle for use as an antirachitic measure in infants is unsound.

Apart from these considerations, reports from reliable observers on the dangers of indiscriminate use of highly concentrated irradiated milk products cannot be over-estimated. Idiosyncrasy undoubtedly plays an important part and it is a well-known fact that a certain type of infant cannot tolerate cod-liver oil in any form. Specially during the summer months toxic and unpleasant symptoms of gastro-intestinal derangement are known to follow a minimum quantity even of ostelin. Every mother in the tropics knows that dermatitis, eczema, and boils result from the use of cod-liver oil. In two cases that came under my observation, the latent period of tolerance, so

common with a new product in cases of unsuccessful feeding of infants, was not observed with irradiated milk. Unlike the older products, irradiated food disagreed from the start and unpleasant symptoms developed immediately every time it was tried.

The manufacturers should arrange for a clean, fresh, and wholesome product, in quality as near as possible to the natural food. The addition of a therapeutic or prophylactic principle for special cases should be left in the hands of the medical attendant. To sell a concentrated prophylactic or therapeutic product for general use is against all principles of dietetics. Why has the vitamin D factor alone been advocated as a prophylactic measure? The calcium-phosphorus ratio as a determining factor in hypovitaminosis and rickets has been well recognised. If the public craze went as far as the calcium-phosphorus ratio, I daresay commercial houses would soon arrange to adjust the percentage of calcium and phosphorus to meet all requirements. And may I also ask why the sound principle of Fowler to inoculate milk with live tubercle bacilli as a prophylactic against tubercle has never been thought of?

I am, Sir, yours faithfully,

F. N. Moos,

RELIEF OF BLINDNESS IN INDIA.

To the Editor of THE LANCET.

SIR,—I feel sure that it is contrary to your intention that the well-meaning leading article in THE LANCET of Dec. 21st should be liable to do an injustice, or create an incorrect impression of the actual facts concerning the relief of blindness in India or the teaching of ophthalmology. As it will appear to ophthalmologists resident in India that it may do so, may I be permitted to point out that some important facts bearing on your article may be found in an editorial in the *Indian Medical Gazette* for September, 1929, on Preventable Blindness in India, and in the report of Sir Norman Walker to the General Medical Council. Many of your readers may not have the opportunity of seeing the *Gazette*. You may therefore consider it desirable to represent some of the views therein expressed.

I am, Sir, yours faithfully,

ROBERT E. WRIGHT.

Government Ophthalmic Hospital, Madras.

ENLARGEMENT OF ADDENBROOKE'S HOSPITAL.—The Hon. Alexandra Peckover has opened a second women's surgical ward of 27 beds. It has been named the Musgrave ward, in recognition of the services to the hospital of Mr. T. Musgrave Francis as chairman for several years of the general committee.

MEMORIAL TO HENRY HILL HICKMAN.—A tablet in memory of Henry Hill Hickman, for the erection of which part of the fund collected has been allocated (see THE LANCET, April 5th, p. 775), was unveiled at the Church of St. Mary the Virgin, Bromfield, Shropshire, on April 5th by Sir St. Clair Thomson. The tablet was dedicated by the Bishop of Hereford.

The ceremony took place in the presence of descendants of Dr. Hickman and the President and five Past-Presidents of the Section of Anesthetics of the Royal Society of Medicine. Among those present were:—

Lord Plymouth, Lieut.-Colonel G. H. and Mrs. Windsor-Clive, Mr. W. Thomson Madin and Mr. C. H. Hawkins (representing Birmingham University Dental School), Dr. J. R. Bulman, Mr. V. Warren Low (treasurer of the Hickman Memorial Fund), Dr. Cecil Hughes (hon. secretary), Mr. Raymond Apperley, Sir Francis Shipway, Dr. Z. Mennell, Mr. M. Ashley Daly, Mr. H. E. G. Boyle, and Dr. Ryan.

The inscription on the tablet is as follows:—

A.M.D.G.: Henry Hill Hickman, member of Royal College of Surgeons; born at Lady Walton in this parish January 27th, baptised in this church January 30th, 1800; died at Tenbury April 2nd, buried in this churchyard April 5th, 1830. This tablet is placed here at the initiative of the Section of Anesthetics of the Royal Society of Medicine as a centenary tribute to the memory of the earliest known pioneer of anaesthesia by inhalation. Honour a physician with the honour due unto him. A.D. 1930.

Obituary.

JOHN YULE MACKAY, M.D. GLASG., LL.D.,
PRINCIPAL OF UNIVERSITY COLLEGE, DUNDEE.

Dr. Mackay, whose death at Broughty Ferry on March 30th was announced in our last issue, was in his 71st year. He resigned the chair of anatomy at the University of St. Andrews three years ago, but continued to hold the Principalship of University

College until his death. John Yule Mackay was born at Inverkeithing, Fifeshire, where his father, the Rev. James Mackay, was minister, and studied at Glasgow University, where he graduated in medicine in 1882, taking his M.D. three years after. For 12 years he was demonstrator in anatomy at the University, and lecturer in embryology.

DR. MACKAY.

In 1894 he was elected to the chair of anatomy at University College, Dundee, in succession to Prof. A. M. Paterson, who was transferred to Liverpool; and later when Paterson was appointed to the Vice-Chancellorship of McGill, Montreal, Mackay succeeded him as Principal of the Dundee College. It was at a time when feeling was running high on the question of union between the College and St. Andrews University, and Mackay played a large part in the delicate negotiations which made the college an integral part of the university in 1897. Quiet and unassuming in manner, Mackay was an effective worker. During his period of office University College rose from a school of nine faculties to one of 14 with two lectureships, and Dundee came to hold its own with its rivals. The staff and students of the college found in their Principal a personality of subtle charm and transparent sincerity, and came to regard him with warm affection.

The services rendered by Principal Mackay to medical education are not yet as widely recognised as they should be. It was in 1902 that he was elected to the General Medical Council to represent the University of St. Andrews, and within four years he became chairman of the Education Committee, holding that position until 1927. Those 20 years were critical for the education of the medical student, especially in preliminary scientific subjects, and almost every year, as the appendices to the Council's minutes testify, reports were drawn up and presented for which Mackay took a large share of responsibility. In 1907 appeared the interim report on the length of the curriculum and ages of students; in 1911 the report on preliminary general examinations; and in 1922 the final report on the revision of the curriculum was approved by the Council, Dr. Mackay being formally thanked from the chair for his services. As a result of these reports the curriculum was rearranged to ensure a period of three years at least between completion of anatomy and physiology and the qualifying examination, opportunities being offered in this period for the study of biology and physiology in their applications to medicine, surgery, and midwifery, and insistence being laid on the principle that throughout the whole period of study the student's

common with a new product in cases of unsuccessful feeding of infants, was not observed with irradiated milk. Unlike the older products, irradiated food disagreed from the start and unpleasant symptoms developed immediately every time it was tried.

The manufacturers should arrange for a clean, fresh, and wholesome product, in quality as near as possible to the natural food. The addition of a therapeutic or prophylactic principle for special cases should be left in the hands of the medical attendant. To sell a concentrated prophylactic or therapeutic product for general use is against all principles of dietetics. Why has the vitamin D factor alone been advocated as a prophylactic measure? The calcium-phosphorus ratio as a determining factor in hypovitaminosis and rickets has been well recognised. If the public craze went as far as the calcium-phosphorus ratio, I daresay commercial houses would soon arrange to adjust the percentage of calcium and phosphorus to meet all requirements. And may I also ask why the sound principle of Fowler to inoculate milk with live tubercle bacilli as a prophylactic against tubercle has never been thought of?

Obituary.

JOHN YULE MACKAY, M.D. GLASG., LL.D.,
PRINCIPAL OF UNIVERSITY COLLEGE, DUNDEE.

Dr. Mackay, whose death at Broughty Ferry on March 30th was announced in our last issue, was in his 71st year. He resigned the chair of anatomy at the University of St. Andrews three years ago, but continued to hold the Principalship of University College until his death. John Yule Mackay was born at Inverkeithing, Fifeshire, where his father, the Rev. James Mackay, was minister, and studied at Glasgow University, where he graduated in medicine in 1882, taking his M.D. three years after. For 12 years he was demonstrator in anatomy at the University, and lecturer in embryology. In 1894 he was

DR. MACKAY.

elected to the chair of anatomy at University College, Dundee, in succession to Prof. A. M. Paterson, who was transferred to Liverpool; and later when Paterson was appointed to the Vice-Chancellorship of McGill, Montreal, Mackay succeeded him as Principal of the Dundee College. It was at a time when feeling was running high on the question of union between the College and St. Andrews University, and Mackay played a large part in the delicate negotiations which made the college an integral part of the university in 1897. Quiet and unassuming in manner, Mackay was an effective worker. During his period of office University College rose from a school of nine faculties to one of 14 with two lectureships, and Dundee came to hold its own with its rivals. The staff and students of the college found in their Principal a personality of subtle charm and transparent sincerity, and came to regard him with warm affection.

The services rendered by Principal Mackay to medical education are not yet as widely recognised as they should be. It was in 1902 that he was elected to the General Medical Council to represent the University of St. Andrews, and within four years he became chairman of the Education Committee, holding that position until 1927. Those 20 years were critical for the education of the medical student, especially in preliminary scientific subjects, and almost every year, as the appendices to the Council's minutes testify, reports were drawn up and presented for which Mackay took a large share of responsibility. In 1907 appeared the interim report on the length of the curriculum and ages of students; in 1911 the report on preliminary general examinations; and in 1922 the final report on the revision of the curriculum was approved by the Council, Dr. Mackay being formally thanked from the chair for his services. As a result of these reports the curriculum was rearranged to ensure a period of three years at least between completion of anatomy and physiology and the qualifying examination, opportunities being offered in this period for the study of biology and physiology in their applications to medicine, surgery, and midwifery, and insistence being laid on the principle that throughout the whole period of study the student's

if any, as appear to the Board to be necessary or convenient the following provisions of the principal Act, that is to say, Section 10 (which regulates the use of mechanical means of restraint), Section 41 (which relates to the letters of patients), Section 42 (which relates to the posting of letters), Section 47 (which relates to the visits of friends), Section 49 (which empowers the Board of Control to order the examination of a patient by two medical practitioners), Section 50 (which relates to inquiries as to property), Section 51 (which relates to searches in the records of the Board of Control), and Section 85 (which provides for the rehousing of patients who have escaped), 5. Modifying and adapting, in relation to institutions maintained by local authorities not being mental hospitals, the provisions of Sections 275 to 278 of the principal Act (which relate to the making of general rules and regulations and the appointment and duties of certain officers).

He said that the first paragraph of the amendment was proposed as a result of representations made to his department that these provisions of the principal Act, which now applied only to certified patients, should apply also, with necessary adaptations, to temporary patients received under Clause 5. He hoped that these precautions would not be necessary in very many cases, but they were being inserted as an additional safeguard to the patient.

Dr. VERNON DAVIES said that he was not altogether prepared to agree that this amendment was an additional safeguard to the patients. What they were doing was to treat temporary patients as certified patients, while not calling them certified. That might be to the advantage of the patient, or it might not. For instance, the provision which regulated the use of mechanical means of restraint might be absolutely necessary, and he thought it should be in the Bill. The provision relating to the letters of patients did not appeal to him to quite the same extent, though it was probably a small point. The authorities would be acting illegally in keeping a definitely certifiable patient as a temporary patient, and perhaps the Board of Control should be given the power to order the examination of a patient by two medical practitioners. He could imagine, however, that it was likely to cause difficulty.

Mr. GREENWOOD said that the Sections in the principal Act were designed for the benefit of a person in a mental hospital. It was surely desirable that these forms of safeguard should apply to people who were only temporary patients. Section 49, which provided for the patient to be examined, did not necessarily mean certification, because the Section ended with the words: "the commissioners may order the patient to be discharged."

Dr. MONNIS-JONES said that when he first read the amendment he was rather inclined to think that they were treating the patients under Clause 5 as if they were certified lunatics, but on reading it more carefully he realised that it was necessary. At any moment these patients might be in such a state that they required in their own interests some of the safeguards which the Minister proposed.

The amendment was agreed to and the Schedule was added to the Bill.

Repeals.

On the fourth Schedule (Repeals), Mr. GREENWOOD moved an amendment to provide that Section 222 of the Lunacy Act, 1800, should continue to operate in the case of voluntary patients who submitted themselves for treatment before this Act came into force. He said that if a person submitted himself for voluntary treatment on the understanding as the law now stood that he could secure his freedom at 24 hours' notice, it would be unfair to tell him that if he was under treatment after January 1st next he could not get out under 72 hours' notice. These people, however, would gradually disappear.

The amendment was agreed to.

The Committee stage of the Bill was concluded, and the Bill was ordered to be reported to the House.

HOUSING (SCOTLAND) BILL.

On April 3rd, Mr. WILLIAM ANDERSON, Secretary of State for Scotland, presented the Housing (Scotland) Bill, a measure to make further and better provision with respect to the clearance or improvement of unhealthy areas; the repair, demolition, or closing of insanitary houses, and the housing of persons of the working classes in Scotland; to amend the Housing (Scotland) Act, 1925, the Housing, &c., Act, 1923, the Housing (Financial Provisions) Act, 1924, and other enactments relating to housing subsidies; and for purposes connected with the matters aforesaid.

SLUM CLEARANCE BILL.

In the House of Commons on April 7th Mr. GREENWOOD (Minister of Health), in moving the second reading of the Housing (No. 2) Bill (the main provisions of which were described in an article in THE LANCET last week), said that the problem of the slums was becoming more difficult year by year, partly because of the progressive decay of the old slums, and partly because of the deterioration in recent years of

more and more property to the slum level. Progress in slum clearance had been deplorably slow. In the 30 years before 1910, 75 schemes were confirmed, of which 43 had been completed. The number of houses and other buildings in the confirmed schemes was approximately 16,000. The number of persons whom it was desired to rehouse was about 74,000. The number of houses that were to be built was 12,000; the number of houses that had already been demolished was between 8000 and 9000; and the number of houses actually completed during the ten years just closed was only 9713—a tragically small contribution to the solution of a problem which had become more serious within the last ten years.

Cumbersome Legal Machinery.

The first reason why they had not been successful in dealing with the problem was the complicated law and procedure at present necessary in order to get a clearance scheme through and completed. The machinery was too cumbersome to be effective. Apart from that difficulties had arisen from the decision of the courts in the case of *Rex v. the Minister of Health ex parte Davis*—what was known as the Derby case. The effect of that decision had been to hold up progress in many parts of the country. That was one of the matters dealt with in this Bill. The second obstacle to a successful attack on the slum problem was the existing grant and all that that involved. It was quite clear that the grant by the Ministry of Health of 50 per cent. of the estimated net annual loss was inadequate and placed too heavy a burden on local authorities. The meticulous and detailed supervision associated with the grant was both a discouragement to local authorities and an inevitable cause of delay. The third reason for their slow progress in recent years was that local authorities had in the forefront of their minds what he might call normal housing requirements, and their energies had gone in that direction. But the time had now arrived when, while pursuing building under the Act of 1921, local authorities should deal in a generous way with the problem of the slums. To enable them to do so it was clear that they must eliminate unnecessary procedure, secure more practical and less cumbersome arrangements, and give the local authorities greater freedom and greater financial assistance. It was important in addition to tighten up in some respects the existing law in order to make it more effective and also to enable local authorities to stop the degradation of new districts towards the slum level. That was broadly proposed in the Bill. Within the limited possibilities of recon-
ditioning he hoped that the powers which the local authorities already had would be used. The Bill introduced rational recon-
ditioning in a new way.

The Financial Aspect.

Dealing with the financial side of the Bill, Mr. Greenwood said that a grant-in-aid would be given to local authorities for dealing with clearance areas, improvement areas, and the demolition of individual houses, and the persons rehoused in any of these ways would be eligible for a grant. The grant was a grant per person—per man, woman, and child. The basis had been fixed so that the proportion of the cost borne by the local authorities should be diminished and the rate charge therefore proportionately reduced. The amount they had arrived at after consultation with the local authorities was 45s. per year for 10 years per person rehoused under this Bill. For agricultural districts the grant would be 50s. per person for 40 years. In London and one or two other places where conditions were such that a considerable amount of rehousing must take place on the site where the people were living, and there must be tenement provision, there would be an additional 25s. per person for 40 years. So far as rents were concerned, the local authority would be able to charge such reasonable rents as they thought fit and to differentiate according to the ability of the tenants to pay. He estimated that it would be possible in the normal case to let half the houses built under this Bill, on a broad average, at least 2s. a week less than the rent at present charged for houses under the existing scheme. That would make it possible to accommodate displaced persons, as to half of them at any rate, in houses where the rent would be as low as 6s. a week plus rates, and the other half in houses at rents of 7s. a week plus rates. That would mean a substantial relief to the hard-pressed slum-dweller. Part IV. of the Bill dealt with rural houses, and its object was to secure more energetic and comprehensive treatment on the rural housing problem.

An Opportunity for Local Authorities.

He hoped that the Bill would commend itself to the House and would be speedily passed into law. He hoped that the local authorities would seize the measure with both hands and extract from it 100 per cent. of what value it contained. He also hoped that with this new measure in their hands the local authorities would pursue to the very

and with real vigour, zeal, and determination the final conquest of the slums. If they did so they would have behind them the active support of a large body of public opinion. When the time came that every overcrowded family had a decent home, whatever it might have cost in treasure, the nation would have rid itself of a gigantic burden of disease, misery, and degradation, and would have done what it ought to have done before and have laid one of the essential foundations of civilised society—the home of the people.

An Unhappy Legacy.

Mr. NEVILLE CHAMBERLAIN said that Mr. Greenwood had treated this subject of slum clearance with an absence of party passion which he warmly welcomed because though on remedies there must, no doubt, be differences of opinion in the House, yet as to the urgency of the problem, the extent of it, and the necessity for finding some remedy all Members of the House were agreed. This generation did not make the slums; they were the unhappy legacy left to us from a time when the principles of public health were not understood and when the standards were very different from what they were to-day. To-day, however, public opinion and the public conscience were awake to the evil of the slums more acutely than ever before. The fact, however, that these conditions had been known to exist since the war, and had not been put right, was most eloquent testimony to the extraordinary difficulty of the problem which Mr. Greenwood was attempting to solve. It certainly had not been for want of trying. He agreed that when they considered the number of houses and persons whose conditions had been improved since 1919 under various slum clearance schemes they appeared deplorably and lamentably small. The worst feature of the slums was overcrowding. If there were no overcrowding the slum problem would be cut in half, and it was the recognition of that fact which since the war had caused the local authorities to concentrate nearly all their attention on the provision of new houses. Their efforts had been remarkably successful, but it was only within the past year or two that he had felt that the local authorities had been sufficiently relieved from the grinding pressure of building new houses to enable them to turn their eyes towards the problem of the slums with any prospect of success. The Bill was not what they had hoped for. It contained very little that was new, but he thought it would produce some effect. The Conservative Party would vote for the second reading and at subsequent stages try to make it a little better and more practicable than it was at present.

A Menace to Women and Children.

Miss LLOYD GEORGE said that the condition of many of the workmen's houses in the country districts was very bad. A report published some years ago showed that in her constituency of Anglesey the death-rate from tuberculosis for women was the highest but one in the whole of the administrative counties in England and Wales. Yet the death-rate for men, who were able to get out into the open air more than the women, was only 22. There could be only one explanation of that, and that was bad housing. The greater menace to the health of the women, who spent the greater part of their lives in dark and ill-ventilated cottages, applied also to young children. It accounted for the fact that in 1927 the infant mortality-rate in Anglesey was equivalent to 93 per 1000, which was alarmingly high.

General Support of M.O.H.'s.

After further debate, Lieut.-Colonel FREMANTLE said he joined in the general feeling of the House that this Bill was a long overdue measure and one which called for the Council of State which the Prime Minister had so cordially asked all parties in the House to combine and create. He had the honour of speaking for the whole body of medical officers of health. As a past President of the Society of Medical Officers of Health, and as one who did perhaps as much as anyone before the war as a medical officer of health to bring before his colleagues in his profession the necessity for dealing with the housing problem, he spoke on their behalf, though without direct mandate, when he said that they wished the greatest measure of support to be given to this Bill in general and at the same time the most meticulous criticism of its details in Committee. They must be perfectly frank in dealing with this problem or they would not be able to deal with it. It was perfectly useless to compare the vital statistics of one slum area with those of the area surrounding it. People lived in the slums by reason of bad fortune of one kind or another. It was often a case of mental deficiency, heredity, and poverty.

Mr. LOGAN: Does the hon. Member suggest that the slum-dweller is a mental degenerate?

Lieut.-Colonel FREMANTLE asked the hon. Member to notice what he had said. Slum-dwellers included mental degenerates. People would not live in slums if they could help it. He believed that his opinion would be endorsed

by medical officers of health. One of the greatest merits of this Bill was its continuity, that it really preserved a general continuity in regard to housing measures which were gradually getting to work. Medical officers of health generally throughout the country recognised that there had been an improvement in housing. They looked forward to the result of the census of next year which would tell exactly the state of overcrowding as compared with 1921. They would then have very definite data on which to proceed. Meanwhile, all the reports of medical officers went to show that there was an improvement in housing accommodation, although there had been a great change in the transportation and disposition of population. There had been a greater gravitation towards Greater London which had made the position in London more difficult. The same was true of other big centres. The Bill was supposed to enable them to close houses and to demolish slum areas and at the same time to build houses. He hoped that it might be so. Medical officers of health had been working for a long time on this question of closure and demolition of houses. Closing and demolishing orders had unfortunately been a dead letter since 1914 and the result was that in a recent report from the medical officers of health in England and Wales, of 2500 houses recommended for closing and demolition only 500 were demolished. That was because there was not a sufficient supply of new houses. No measure—not even the present Bill—would be any good unless it helped to provide new houses in which to rehouse persons removed from the slum areas. One very material reason for delay in clearing slum areas was the Rent Restriction Act which was not dealt with in this Bill. A very great difficulty had always been that where there was a recognised injustice under the law the local authorities would not put it into force. Medical officers of health would welcome certain parts of the Bill. In Clause 17 there was a very valuable power which enabled part of a house to be closed without closing the house altogether. There was also valuable provisions in the improvement clause which were really the only novelty in the Bill. The provision for the aged should be extended. The method of subsidy was also a valuable feature. It attacked overcrowding which was really the greatest difficulty of all.

The debate was adjourned.

The Financial Resolution.

On April 8th the debate on the second reading of the Housing (No. 2) Bill was resumed.

The second reading was agreed to without a division.

The House then went into Committee on the financial resolution in connexion with the Bill.

Miss SUSAN LAWRENCE (Parliamentary Secretary to the Ministry of Health) said that the Government did not give any estimate of the cost of the scheme because they did not know what the cost would be. If the response of the local authorities was satisfactory the cost would be very great. If, on the other hand, the scheme was a failure it would cost nothing.

The resolution was agreed to.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 2ND.

Ministry of Health and Test Work.

Mr. HORE-BELISHA asked the Minister of Health whether he proposed to publish the Report of the Ministry's inspectors on the position of test work.—Mr. GREENWOOD replied: I propose to publish the report on the inquiry.

Scientific Inquiry on Anthrax.

Dr. SALTER asked the Home Secretary whether he was now in a position to present an interim report upon the investigations carried out by the Scientific and Industrial Research Committee on the disinfection of hides and skins from anthrax.—Mr. SMORR, Under Secretary to the Home Office, replied: These investigations are being carried on not by the Department of Scientific and Industrial Research, but by the British Leather Manufacturers' Research Association, but some account of the progress of the research is given on page 130 of the recently published annual report of the department for 1928-29 (Cmd. 3471). I understand that a full account of the results will probably be published in a scientific journal, but my right hon. friend proposes to consult with the Association as to whether some advance statement should not be issued, and he will communicate the result to my hon. friend in due course.

THURSDAY, APRIL 3RD.

Marriage of Mental Defectives.

Mr. SORENSSEN asked the Minister of Health whether he had any information respecting the marriage of mental defectives and their offspring; and whether he contemplated

taking steps to prohibit such marriages.—Mr. GREENWOOD replied: References have been made to this matter from time to time in the reports of the Board of Control. Legislation would be necessary in order to prohibit the marriage of mental defectives; and I cannot at present undertake to introduce a measure for this purpose.

Colonies for Mental Defectives.

Mr. SORESENSEN asked the Minister of Health how many colonies for mental defectives existed in England and Wales, the total number of patients and attendants respectively; and the total cost; and whether he contemplated encouraging the further establishment of these colonies.—Mr. GREENWOOD replied: There are 35 institutions certified under the Mental Deficiency Acts which may be regarded as colonies, but they are in widely divergent stages of development. The total number of patients is at present 10,592, but I am not in a position to state the number of attendants or the total cost. The cost of colonies is under consideration by a committee recently appointed, and their advice must have a bearing on the question of further provision of accommodation of this type.

Board of Control and Mental Treatment.

Mr. KINLEY asked the Minister of Health the average number of patients per doctor in the institutions under the jurisdiction of the Board of Control.—Mr. GREENWOOD replied: As regards institutions under the Lunacy Act, the average number of patients to each member of the resident medical staff is: (a) in county and borough mental hospitals, 250; (b) in registered hospitals, 61; and (c) in licensed houses, 35. Most of these institutions have, in addition to their resident staff, a number of visiting consultants. In mental deficiency institutions the average number of patients to each member of the staff, resident and non-resident, is 111.

Mr. KINLEY asked the Minister of Health the number of institutions under the jurisdiction of the Board of Control in which the approved accommodation was in excess of normal requirements; and what was that excess.—Mr. GREENWOOD replied: There are 44 local authorities under the Lunacy Act who have accommodation in excess of that required for patients within their own area; and the total number of beds is at present 5272. Most of this surplus accommodation is, however, occupied by patients received under reception contracts from other local authorities who have insufficient accommodation or do not own a mental hospital. I am informed that private institutions under the Lunacy Act have sufficient vacant beds to meet normal requirements. In the case of mental deficiency institutions there is no accommodation in excess of normal requirements.

Mr. ROBERT RICHARDSON asked the Minister of Health in how many instances during the past year the Board of Control, in fulfilling their duty of scrutinising documents of certification had discovered that no reason had been stated (as required by Section 32 of the Lunacy Act, 1890); as to why the usual medical attendant of the patient had not been consulted; or if it was aware that the omission to give this reason constituted contravention of an important safeguard; and if he would see that in future that no such omission was allowed to pass unnoticed.—Mr. GREENWOOD replied: Statistics are not available in regard to this point. But the omission to which my hon. friend refers is a contravention of Section 31 of the Lunacy Act, and the Board of Control return for insertion of the necessary particulars all reception documents which do not comply with the requirements of that Section.

State Grant for Medical Research.

Dr. FORGAN asked the Secretary to the Treasury, in view of the inadequacy of the present endowment of medical research, what action was proposed to take to increase the amount of the annual grant in aid.—Mr. PETHICK-LAWRENCE replied: The present annual grant in aid of the Medical Research Council is £148,000, and I have no reason to think that it is inadequate. My hon. friend must understand that this is by no means the only contribution made by the State to medical research.

Imported Milk and Tuberculosis.

Brigadier-General CLIFFORD-BROWN asked the Minister of Health the amount of liquid milk and liquid cream imported into this country in 1929; from what countries they came; and what precautions were taken to see that they were free from tuberculosis.—Mr. GREENWOOD replied: I am informed that 58,460 cwts. of milk and 138,004 cwts. of cream were imported into Great Britain and Northern Ireland in 1929. All the milk, except 400 cwts. from Denmark and the Netherlands, came from the Irish Free State. I am sending the hon. Member a statement showing the countries from which the imports of cream were received. Imports of milk from outside the British Islands are subject to examination for tubercle under the Imported Milk Regu-

lations. There is no examination of imported cream for this purpose.

Small-pox Contacts and Vaccination.

Mr. GROVES asked the Minister of Health if he would issue a memorandum to public medical officials deprecating the vaccination of persons who had been in contact with small-pox, seeing that in cases where the small-pox had already been contracted the operation could only add to the patient's troubles, and in those cases where it had not been already contracted after such exposure the imposition of the operation was, ipso facto, unnecessary.—Mr. GREENWOOD replied: No, Sir. I do not think that I should be justified in adopting the course suggested. I am advised that vaccination, if performed sufficiently soon after exposure to small-pox infection, usually prevents an attack of the disease. If vaccination is performed too late to prevent the disease being contracted it may, nevertheless, modify the severity of the attack.

Management of London Lock Hospital.

Mr. ERNEST BROWN asked the Minister of Health if he was now in position to announce the reforms undertaken by the board of the Lock Hospital; whether any women had been appointed to its governing board; and, if so, what were their names.—Mr. GREENWOOD replied: The governing body of this hospital have given effect to a number of the recommendations contained in the papers presented to Parliament last July, and I understand that further improvements are in contemplation. I do not consider that the best interests of the hospital would be served by publishing details at the present time of the reforms already effected. As regards the remaining parts of the question, the board of management of the hospital includes the following ladies: Mrs. Hatfield, J.P., Councillor Mrs. Hendin, J.P., Commissioner Mrs. Lamb, J.P., Lady Leitrim, Miss E. E. MacNeill, and Miss Mowll.

Psittacosis.

Mr. GRAHAM WHITE asked the Minister of Health the number of cases of psittacosis notified during the month of March.—Mr. GREENWOOD replied: Psittacosis is not a notifiable disease, but my department has received information of 20 cases of illness which commenced last month, and in which the patients had been associated with sick parrots. I am advised, however, that in the present state of knowledge of psittacosis it is not possible to say definitely how many of these persons were in fact suffering from that disease.

Birth Control Information.

Mr. R. S. YOUNG asked the Minister of Health whether it had been reported to him by his medical officers that there were any demands or requests for birth control information from mothers at subsidised welfare centres.—Mr. GREENWOOD replied: Such requests are only occasionally reported by the medical officers of the department.

Lead Paint Prosecutions.

Mr. MCKINLAY asked the Home Secretary the number of prosecutions arising out of the evasion of the Lead Paint Regulation.—Mr. CLYNES replied: These regulations came into force on Oct. 1st, 1927, and no prosecutions were taken in that year. During 1928 and 1929 and the first three months of 1930 proceedings were taken in respect of 33 contraventions and convictions obtained in 31 cases.

MONDAY, APRIL 7TH.

Conditions in Boot Industry in East London.

Mr. MALONE asked the Home Secretary whether he had received the report on conditions of employment in the boot industry in the East End of London, prepared by Dr. A. D. Denning for the Boot Manufacturers' Federation and the National Union of Boot and Shoe Operatives; and, if so, what action he proposed to take.—Mr. CLYNES replied: Yes, Sir. I have now received and perused this report. I find that it draws a most unfavourable picture of the conditions under which this industry is carried on in the East End of London, but that, so far as concerns matters within the purview of my department, the conclusions appear to be based not on facts ascertained by personal observation of the conditions at the works concerned, but almost entirely on impressions derived from unverified ex parte statements. I understand that though Dr. Denning was offered facilities by the Factory Department for the purposes of his investigation he has never discussed the position with the department, and the chief inspector informs me, after consulting the whole of the staff in the districts concerned, that they are unanimously of opinion that the report gives a very exaggerated account. I find also that the report contains statements conveying serious reflections not only on the competency of the factory inspectors, but also on their attention to duty and even on

their honesty—as, for example, that the inspectors have favoured Jewish as against British employers, and that they are open to accept bribes. These allegations which, unless supported by detailed and reliable evidence, ought never to have been put forward, are strongly repudiated by the staff, and I cannot but express my surprise and regret that a report containing such allegations and compiled on the basis I have indicated should have obtained currency before any attempt had been made to subject the accuracy of the statements it contains to an independent test. I understand that the report has now been considered jointly by the Federation of Boot Manufacturers and the National Union of Boot and Shoe Operatives, and that a committee has been appointed to consider what steps should be taken. The chief inspector informs me that he has been invited, and has agreed, to attend a meeting of this committee, and I propose to await the result of that meeting before considering what action, if any, it behoves me to take.

Inspection of Imported Meat.

Mr. THORNE asked the Minister of Health if he was aware that the examination of Argentine mutton for caseous lymphadenitis was becoming less stringent in all centres outside the City of London; that in the ports of London, Liverpool, and Southampton the work of cutting and examining the glands of the sheep was left to dock workers or employees of the importing firms; that carcasses had been passed by the port sanitary authority and afterwards condemned by the City of London inspectors; and whether he was prepared to issue a circular instructing port medical officers to carry out examinations effectively.—Miss SUSAN LAWRENCE (Parliamentary Secretary to the Ministry of Health) replied: The answer to the first part of the question is in the negative. My right hon. friend understands that at some ports skilled men are specially employed whose business it is to cut and expose glands for inspection by officers of the Port Sanitary Authority. With regard to the third part of the question, my right hon. friend is informed that it is not the practice at the Port of London to inspect meat which is destined for the city markets, and will be inspected there. A conference between the medical officers of health of the ports principally concerned and officers of my department took place recently, and the conclusion was reached that no relaxation should be made of the present arrangements for examination. My right hon. friend does not think that any circular on the subject is required at present.

TUESDAY, APRIL 8TH.

Medical Experts and Seven-year Limit Pension Cases.

Mr. GRAHAM WHITE asked the Minister of Pensions the number of seven-year limit cases submitted to the independent medical experts and the results.—Mr. F. O. ROBERTS replied: Up to date about 25 cases of material doubt or difficulty have been or are being referred to the independent medical consultants for consideration and advice, but not more than nine of these have so far been decided, with results unfavourable to the claimants. These figures are not, however, representative as the new arrangements have only quite recently reached their full operation. I may add that during the same period 227 applications have been admitted without reference to the consultants.

Extension and Coördination of Insurance Services.

Mr. MCENTEE asked the Minister of Health whether he was considering the extension and coördination of the national insurance services; and whether he would include in any new legislation for that purpose facilities for small shopkeepers and business men with limited incomes to become voluntary contributors for health purposes.—Miss S. LAWRENCE replied: These matters come within the scope of the Cabinet Committee engaged on a general survey of the existing insurance and pensions legislation.

BELLE VUE SPA, TREFRIW, NORTH WALES.—New pump rooms at this spa, where all forms of arthritis are treated, are to be opened on April 26th by Sir W. Arbuthnot Lane, supported by Dr. R. Fortescue Fox.

RESIDENTIAL SPECIAL SCHOOLS.—The Shaftesbury Society and Ragged School Union is extending the Victoria Home for Crippled Children, Bournemouth, so as to receive 20 more children from 2 years and upwards, following their hospital treatment. The accommodation at the Russell Cotes School of Recovery for delicate children at Parkstone has been increased by 30 more beds. The accommodation in the four seaside residential schools certified by the Board of Education will then be enlarged to 270 places.

Medical News.

UNIVERSITY OF BRISTOL.—At a recent examination the following candidates were approved:—
M.D.—J. F. O. Bodman and T. F. R. Hewer.

LONDON CLINICAL SOCIETY.—A clinical meeting of this society will be held on April 15th at the London Temperance Hospital, where cases will be on view from 8.30 P.M.

ROYAL LONDON OPHTHALMIC HOSPITAL.—The Gifford Edmonds' Prize for 1930, offered for an essay on Central Scotoma, its Pathology and Clinical Significance, has been divided between Dr. Rosa Ford and Miss Laura M. Ligertwood, F.R.C.S.

PRESENTATION TO DR. JOSEPH BEARD.—Dr. Beard, of Carlisle, who has retired from the medical officership of the town, was, on April 1st, presented at a representative gathering of citizens with a casket and cheque in recognition of his 22 years' service.

NATIONAL SMOKE ABATEMENT SOCIETY.—A public conference on by-laws under Section 5 of the Public Health (Smoke Abatement) Act, 1926, will be held on May 2nd at 71, Eccleston-square, Westminster, S.W., at 3.30 P.M. The discussion will be opened by a paper to be read by Mr. C. J. Allpass, chairman, Public Control Committee, London County Council.

INSTITUTE OF PATHOLOGY AND RESEARCH, ST. MARY'S HOSPITAL.—The programme of the year's course of lectures on Pathological Research in its Relation to Medicine has reached us. The lectures will be given as usual in the lecture room of the bacteriological department of the Institute on Thursday afternoons at 5 P.M., beginning on April 24th, when Sir Almroth E. Wright will lecture on Twelve Years' Work on Immunisation of the Blood in vitro. Subsequent lectures will be as follows: May 1st, Prof. John Mellanby, Absorption from the Alimentary Canal. 8th, Dr. W. E. Gye, the Action of Antiseptics on the Virus of Filtrable Tumours. 15th, Dr. Leonard E. Hill, the Physiology of Diving. 22nd, Prof. C. A. Lovatt Evans, Stages in the Investigation of the Physiology of the Heart. 29th, Sir Thomas Lewis, Reactions of the Skin to Cold. June 5th, Prof. G. E. Gask, the Value of Radium in Surgery. 12th, Colonel L. W. Harrison, Development of the Modern Treatment of Syphilis.

MEDICAL SUPERINTENDENTS' SOCIETY.—The annual dinner of this society took place at the Holborn Restaurant on March 28th, Dr. E. W. G. Masterman, president of the society, being in the chair. Amongst the 93 members and guests present were Dr. Barrie Lambert, chairman of the Central Health Committee, London County Council; Dr. W. Allen Daley, Dr. J. Brander, and Dr. J. A. H. Brincker, principal medical officers of the Council; and Dr. J. J. Buchan, president of the Society of Medical Officers of Health. Dr. Daley, in proposing The Society, recalled incidents in its 43 years' history. Dr. Masterman, in reply, said the name of the society had been changed so as to include medical superintendents of all public hospitals and of voluntary hospitals and whole-time medical officers in responsible charge of patients in public hospitals or institutions for the sick. Dr. Lambert, replying for The Guests, emphasised the need for coöperation between medical superintendents and the London County Council in its enormous task. Dr. Buchan spoke of liaison between the curative and preventive sides of medicine.

SEAMEN'S HOSPITAL SOCIETY.—A dinner was held at the Mansion House, London, on April 8th, in aid of the funds of the Hospital for Tropical Diseases, Endsleigh-gardens. The Duke of York, who presided, said that the work of the hospital fell into three main sections: treatment, research, and education. In addition to officers and men of the Mercantile Marine, persons of every race, nationality, and creed received treatment. Research into the causation and prevention of tropical diseases carried on in the laboratory of the hospital had resulted in discoveries which had rendered habitable vast tracts of country, while the instruction given to members of the medical profession destined to practise in the tropics carried expert knowledge to every corner of the tropical world. The new lecture theatre would be known as "The Manson Clinical Lecture Theatre" to remind students of the source of inspiration from which their knowledge sprang. The necessary alterations and extensions to the hospital would cost £35,000. Lord Passfield praised the work of the School of Tropical Medicine, Sir Arthur Clarke and Dr. G. Carmichael Low replied. Sir Leslie Wilson announced that promises for £10,000 had been handed to the Duke of York during the evening.

BOMBAY MEDICAL COUNCIL.—At a meeting of the Council held on Feb. 10th, Major-General W. H. O. Forster, I.M.S., the new President, was introduced to the Council by Sir Temulji Nariman. The Council resolved to recognise as an additional qualification the Diploma in Ophthalmology now granted by Bombay University.

ROYAL SANITARY INSTITUTE.—A meeting is to be held on May 2nd, in the Town Hall, Tunbridge Wells, when discussions will take place on the Maternity Home as a Health Asset, to be opened by Dr. F. Churchill Linton, and on Can the Slum be Abolished? to be opened by Mr. H. T. Taylor.

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.—The sixteenth annual conference will be held on July 3rd, 4th, and 5th next, in the British Medical Association House, London. It is proposed to concentrate attention on the effects on the Tuberculosis Campaign of the Local Government Act, 1929. The subject will be introduced by Sir George Newman, followed by Dr. John Parlane Kinloch.

ROLLER SKATING ACCIDENTS.—The Board of Management of Workshop Hospital has decided that patients suffering from accidents while roller skating shall not, in future, receive free treatment, even although they are members of the Contributory Scheme.

EAST LONDON HOSPITAL FOR CHILDREN.—At the annual meeting of this hospital last week Sir Percy Shepherd, who presided, pointed out that the completion of the buildings could no longer be postponed, the accommodation for the nursing staff alone having been severely criticised by King Edward's Fund as totally inadequate to modern requirements. The work will cost £25,000.

SCUNTHORPE ISOLATION HOSPITAL.—This hospital at Brumby, near Scunthorpe (Lines.), was opened last week by Lord Heneage, the chairman of the Lindsey County Council. The accommodation includes a scarlet fever block, a cubicle block of eight beds separated by glass partitions for other fever cases, a tuberculosis pavilion, and a children's playroom.

THE DIFFICULT CHILD AS A MEDICAL, SOCIAL, AND PSYCHOLOGICAL PROBLEM.—A series of six lecture-discussions on this subject will be delivered by the officers of the Child Guidance Clinic of the Jewish Health Organisation of Great Britain, on Mondays and Thursdays, at 5.15 p.m., beginning on May 19th. The meetings will take place at Toybee Hall, Commercial-street, London, E. Dr. F. C. Shrubsole will take the chair at the first lecture, on the General Nature and Scope of the Problem and its Treatment, which will be delivered by Dr. Emanuel Miller. Dr. Noel H. M. Burke will speak on the Management of a Clinic on May 22nd and on Physical Factors on June 2nd. Dr. Emanuel Miller will give the concluding lecture on the Role of the Psychiatrist on June 5th. Tickets for the course, which is meant chiefly for officers and workers connected with schools, homes, and clubs in the East End of London, may be obtained from Child Guidance Clinic, Jews' Free School, Bell-lane, Spitalfields, London, E.

Medical Diary.

SOCIETIES.

CHELSEA CLINICAL SOCIETY.

TUESDAY, April 15th.—7.30 P.M., Dinner at the Hotel Rembrandt, Thurlow-place, S.W., followed by a discussion on Coughing. Openers: Dr. R. A. Young and Mr. Philip Franklin.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

NORTH-EAST LONDON POST-GRADUATE COLLEGE. Prince of Wales's General Hospital, Tottenham, N.

MONDAY, April 14th.—2.30 to 5 P.M.: Medical, Surgical, and Gynaecological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose, and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Med., Surg., Nose, Throat, and Ear Clinics. Operations.

CITY OF LONDON MATERNITY HOSPITAL. City-road, E.C.

TUESDAY, April 15th.—3 P.M., Mr. A. L. Walker: The Management of Tokemia.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL. FRIDAY, April 18th.—P.M., Mr. J. D. McLaggan: The indications for the Removal of Tonsils and Adenoids in Children.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION. WEDNESDAY, April 10th.—4.15 P.M. (at the Western Infirmary), Dr. John Grace: Medical Cases.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE. TUESDAY, April 15th.—4.15 P.M., Mr. J. Howson Ray: Hydatid of the Liver.

Appointments.

ADAMSON, A. F., M.D., Ch.B. Edin., has been appointed Medical Officer of Health, Hendon.

ADAMSON, OSWALD J. W., LL.R.C.P. Lond., M.R.C.S., Honorary Clinical Assistant to the Ophthalmic Department, Royal Sussex County Hospital, Brighton.

BAINBRIDGE, MARION L., M.B., Ch.B. Manch., Asst. Welfare Medical Officer, Durham County Council.

COLVILLE, E. T., M.D., B.S. Durh., D.P.H., Medical Officer of Health, Wellington.

DRURY, R. K., M.D., B.Ch., D.P.M. (T.G.D.), Medical Superintendent of the Leicester and Rutland Mental Hospital, Narborough, nr. Leicester.

KELLY, D. H., M.B., B.Ch., N.U.I., House Surgeon, North Riding Infirmary, Middleborough.

MORLEY, J. M.B., Ch.M. Manch., F.R.C.S. Eng., Lecturer in Systematic Surgery in the University of Manchester.

PURCE, G. R. B., M.B., M.Ch. Belf., D.P.H., Hon. Asst. Surgeon, Royal Victoria Hospital, Belfast.

RAYNER, E. C., M.B., B.Ch. Camb., Certifying Surgeon, under the Factory and Workshop Acts for the Hythe District of the County of Kent.

Queen Charlotte's Maternity Hospital: JENNINGS, H. T., M.B., Ch.B., F.R.C.S.E., Senior Resident Medical Officer;

PLW, J. D., M.R.C.S., LL.R.C.P. Lond., Assistant Resident Medical Officer; WRIGHT, ELAIN, M.B., B.S. Lond., District Medical Officer; PARSONS, FLORENCE, M.R.C.S., LL.R.C.P. Lond., Resident Anesthetist.

Certifying Surgeons under the Factory and Workshop Acts: CHILLINGWORTH, H. F., LL.R.C.P. Lond., M.R.C.S. (Bodmin, Cornwall); and LATHAM, T., LL.R.C.P. Lond., M.R.C.S. (Sandbach, Chester).

Medical Referees under the Workmen's Compensation Act: ALCOCK, A., M.B., B.S. Lond. (Cirence 53); GEDDIE, M.B., Ch.B. Aberd. (Cirence 4); and STALKER, J. M., M.B., Ch.B., St. And. (Dundee District of Forfar).

Vacancies.

For further information refer to the advertisement columns.

Aberdeen City Hospital for Sick Children.—Two H.P.'s and Two H.S.'s.

Aden Settlement, Arabia.—M.O.H. \$800rs. per mensem.

Albion, Canada.—Municipal Doctor. \$2000 per annum.

Aylesbury, Royal Buckinghamshire Hospital.—Res. M.O. At rate of £200.

Barrow-in-Furness, North Lonsdale Hospital.—H.S. £175.

Basingstoke, Park Prevel Mental Hospital.—Jun. Asst. M.O. £350.

Bath, Royal United Hospital.—H.S. Asst. H.S. At rate of £150 and £100 respectively. Also H.P. £120.

Belfast County Hospital.—H.S. At rate of £175.

Bell Memorial Fellowship for Medical Research.—Jun. Fellows. £400.

Birmingham General Hospital.—H.P. £70.

Boltongrove Hospital, Wandsworth Common, S.W.—H.S. At rate of £120.

Bournemouth County Borough.—Asst. M.O., Sec. £650.

Bradford Royal Infirmary.—H.P. and H.S. Each £150.

Brighton, Royal Alexandra Hospital for Sick Children.—H.P. £100.

Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.

British Guiana, Georgetown.—M.O.H. £800.

British Medical Association.—Asst. Med. Secy. £1000.

Burnley, Victoria Hospital.—H.P. At rate of £150.

Burton-on-Trent General Infirmary.—H.S. £150.

Cardiff Royal Infirmary.—Aural H.S. At rate of £75.

Carshalton, Queen Mary's Hospital for Children.—Jun. Asst. M.O. £500.

Charing Cross Hospital, W.C.—Physician for Mental Disorders.

Chester Royal Infirmary.—Hon. Surgeon.

Chester Royal Infirmary, Orford-road, E.—Sen. Res. H.S. At rate of £150.

Congnaught Hospital, E.—Sen. Res. H.S. At rate of £100. Also M.O. for Electro-therapeutic Sec. Depts.

Dundee Royal Infirmary.—Two Asst. Visiting M.O.'s.

Durham County Council.—Asst. M.O. for Public Services. £800.

Durham County Hospital.—Jun. H.S. At rate of £120.

East London Hospital for Women and Children, Shadwell, E.—Cas. O. At rate of £125.

Edinburgh Corporation.—M.O.H. £1500.

Elizabeth Garrett Anderson Hospital, Euston-road.—Asst. Radiologist. £100.

Erictina Hospital for Children, Southwark, S.E.—H.S. At rate of £150.

Exeter, Royal Devon and Exeter Hospital.—H.S. to Spec. Depts. At rate of £150.

Folkestone Borough.—Asst. M.O.H. £600.

Gloucestershire Royal Infirmary.—2nd H.S. At rate of £100.

Halifax Royal Infirmary.—First H.S. also Third H.S. At rate of £175 and £100 respectively.

Hampstead General and North-West London Hospital, Haverstock Hill, N.W.—H.S. At rate of £100.

Harrowgate General Hospital.—M.O.H. £1500.

Hong-Kong.—Medical Officers.

Hong-Kong.—Epilepsy and Paralysis, Maide Tala, W.—Res. M.O.

Also H.P. At rate of £150 and £100 respectively.

Hospital for Sick Children, 61, Ormond-street, W.C.—Res. M.O.

for County Branch Hospital, Tufordworth. At rate of £250.

Hospital for Women, Soho-square, W.—Res. M.O. At rate of £100.

Improvement the Result of Scientific Discovery.

The improvement in the West African figures of death and invalidings since the beginning of this century are in the main the direct outcome of certain scientific discoveries made chiefly by medical men of many different nationalities and made, many of them in parts of the world quite remote from each other and from West Africa.

Manson, a British subject, in 1877 in China discovered that filaria undergoes development in a mosquito. Laveran, a Frenchman, in 1880 in Algiers discovered the parasite of malaria. Smith and Kilborne, Americans, in 1893 in America showed that protozoa in the shape of *Babesia* could be transmitted by ticks. Bruce, a British subject, in 1895 in South Africa associated trypanosomiasis of cattle with the tsetse-fly. Eijkman, a Dutchman, in 1897 in Java showed that fowls took polyneuritis when fed exclusively on decorticated rice. Ross, a British subject, in 1897 in India showed that human malaria parasites commence to develop in anopheline mosquitoes; in 1898 he proved the whole cycle of bird malaria in culicines. Grassi, an Italian, in 1899 in Italy confirmed Ross's work on human malaria. Looss, a German, in 1901 in Egypt demonstrated how hookworm infection occurs. Carrol, Reed, Lazear, and Agramonte, an American Commission in 1901, in Havana proved that *Aedes* transmits yellow fever.

These brilliant discoveries in all parts of the world, discoveries made before this century was well begun, were what has rendered possible the progress in health of which the West African Colonies can boast to-day. They form the basis of subsequent work by innumerable observers; every year sees new discoveries and it is the application of the combined results by medical men and sanitarians which has produced the change in the death- and invaliding-rates which I have just given you and which has altered completely our outlook on West Africa, as on the whole of the tropical regions of the world.

Yet this dramatic change is not without its drawbacks; there is, in fact, at present somewhat a danger of an overswing of the pendulum; although the change from a quite obsessional pessimism to a rational optimism as regards West African health conditions has occurred in such a short space of time people are already beginning to lose sight of the fact that it is only by the rigid application of knowledge and by unremitting attention to the details of self-protection that such encouraging results have been obtained in the past and that they can be continued in the future, at least in the near future. There is, I think, a possibility that too much apprehension may be succeeded by over-complacency. People in general, too, have an overestimated idea of what has actually been accomplished in regard to certain matters. For example, I have often been asked about the prevalence of such things as mosquitoes and tsetse-flies in West Africa by people who honestly believe that these things have become quite scarce as the result of the application through sanitation of the findings of research. It is true that such insect pests as those mentioned and many similar carriers of human diseases may be quite scarce in a given compound or a single village or even in a particular town, but to speak of any of them as being scarce in West Africa as a whole is like affirming that grains of sand are already scarce in the Sahara.

As an illustration of how successful the results of research have been in limiting the mortality in West Africa, I would mention that many people are of the opinion that there is little more to be done. Men who had commercial interests in the tropics 25 to 30 years ago were compelled to take some action owing to the very fatal effects of West African diseases, which rendered the employment they offered entirely unattractive, at least to those of their employees who desired to prolong life. Medical research was called for with insistence, and there were in those days

individuals interested in trade with West Africa who were prepared to expend large sums for the purpose of research and sanitation. These men have been succeeded by a generation which has never experienced a death-rate of 70 per 1000 and which

Gangosa (*Rhinopharyngitis mutilans*), showing perforation of the hard palate in patient with yaws history.

sees no reason to be dissatisfied with a death-rate of somewhere about 7 per 1000.

Research has Outstripped Practice.

It is, I think, quite correct to say that research into the causation of disease has outstripped sanitation. A great deal of work is therefore being done at present by sanitarians which has the immediate aim of devising means of applying, in places like West Africa, the necessary and known remedies with the least possible expense. This question of expense is crucial; West Africa is no Panama; if we could act to-day in a manner quite regardless of expense, I have no hesitation in saying that we could deal with the health problems in West Africa as a whole in a way which would rapidly effect a complete transformation. But, unfortunately, we are faced with the insuperable obstacle of expense. The task before sanitary officers in the tropics now is to invent means of eradicating disease, not at a cost which the future result might easily justify, but at a cost which the present resources of the colonies permit. In the ultimate result I do not anticipate that much better figures than those recorded for non-native officials, and which I have given you to-day, can reasonably be expected; but what may be expected is that after a period of oscillation satisfactory figures will be maintained with much less effort than is required at present, on the part not only of the sanitary officers but also of every white individual, European or American, living in West Africa.

I should like to say a word with reference to certain diseases which in my opinion require further elucidation or prevention. Reverting for a moment to the figures quoted we find that of the 27 deaths recorded for 1928 among the non-native officials in West Africa, 20 were directly due to disease. Although many different diseases claim victims in West Africa, such diseases as yellow fever, alarming and fatal as they are, do not cause the steady and serious mortality that is produced by certain others which appear less conspicuous solely because they do not involve quarantine regulations. Of the 20 fatal cases referred to, death was ascribed to malaria directly in two, to malaria indirectly in one, to blackwater fever directly in four, and to blackwater fever indirectly in one. The total cases therefore in which either malaria or blackwater fever was the cause of death was eight—that is, 40 per cent. This is a figure which suggests that malaria, and even more so blackwater fever, require further study. Unfortunately, no investigation upon malignant tertian malaria in its association with

blackwater has ever been carried out on a scale commensurate with the importance of these two diseases to white residents in West Africa and elsewhere. It has been left to a few isolated individuals or small groups of workers to make such scanty observations as were possible or to formulate theories as to causation and prevention. It appears to me to be fully time to examine the theories already put forward, and if these prove inadequate to inaugurate a definite scheme of continuous research to discover the genesis of blackwater fever. Failing this, it would be best to act on the assumption that the causation of the disease is closely associated with malaria. Taking as probably correct, what many of us have long believed, that blackwater fever is a phenomenon dependent upon malignant tertian malaria or upon its sequelæ, one might expect substantial results from attacking the problem from the sanitation and personal prophylaxis point of view—that is, by concentrating on still further reducing the infection with malignant malaria, and by adequate treatment of the malaria cases which occur.

Segregation.

There are one or two other points which I should like to mention; for example, it may be well to spend a few moments in considering certain aspects of the white man's contacts with the native; apropos of this it will be natural to touch upon the subject of segregation and the domestic employment of natives. The

subject of segregation has been the cause of much heart-burning and acrimonious discussion, yet it is difficult to understand why this should be so, as the principle underlying the whole question appears to be extremely simple. If a non-immune person has to live with an infected—e.g., a malaria-infected population, there are two ways open to him by which he can endeavour to avoid infection. The first is to place his

quarters so far from that population's quarters that the infective anopheline mosquitoes are unlikely to reach and infect him; this is segregation. The second is either to treat and cure the disease in the infected population or to eliminate all mosquitoes or both; this is sanitation, and usually it is a much bigger proposition. Segregation is advisable and necessary wherever sanitation is impossible or imperfect. The segregation of a European from infective native quarters is no more a slight on the native than is the same European's practice of living in a mosquito-proof house in the midst of an infected population. The object and, with adequate care and a proportion of good luck, the result is the same in both cases—namely, the successful avoidance of the bites of the infective anophelines. But while segregation is no

reflection on the native qua native and is a necessary and unavoidable proceeding in many instances, it is none the less an admission that preventive sanitary measures are either lacking or have failed, and in this sense it is a reflection upon our success in sanitation. The ill-results of non-segregation in infective populations with inadequate sanitation are exemplified in the experience of places like Dakar and yellow fever.

While on the subject of segregation I might refer to the groups of Asiatics and particularly the Syrian. The Syrian in West Africa lives in conditions which are the very reverse of segregation, and as a

consequence he constitutes somewhat of a problem from the medical point of view. In order that you may understand the position I may say that in the Protectorate of Sierra Leone, for example, one finds the Syrian small trader everywhere, usually ensconced in the chief's compound and often in the house next to the chief. In many districts he is the self-constituted principal adviser of the chief, and he has incidentally collected into his own hands much of the trade of the various colonies, for example, the whole of the kola trade and much of the internal rice trade of Sierra Leone; this he has been able to do largely by a policy of non-segregation, by the process of living with and among the natives pretty much on their own level, a procedure attended doubtless by some financial advantage, but certainly by no gain in health. As a result of his lack of segregation the Syrian is constantly and severely attacked by many diseases acquired from the native. He is always getting malaria, blackwater, and other diseases; in fact, he performs the function of a sort of human indicator of the prevalence of various tropical diseases in endemic areas. There are doubtless excellent reasons of which I am unaware why he should be persona grata in British West African colonies, and it is possible that he may never attain there the dimensions of a political problem, but certainly from a health point of view his presence in British West Africa appears neither beneficial to us nor particularly fortunate for himself, and he does constitute a minor medical problem.

House Servants.

The case of house servants employed by white residents in West Africa may also be mentioned briefly. In Sierra Leone I have had the experience of engaging a cook who, on the day of his engagement, armed with the usual testimonials, was suffering from acute amoebic dysentery. Fortunately he was too ill to work and complained, and his condition was diagnosed, and he was sent to hospital. This illustrates a danger to the health of white residents in the tropics to which they should not be subjected, and which is largely avoidable. I have advocated the medical examination of cooks and house servants and their registration as a necessary means of protection for the health of their white employers. In

Gangosa; cartilage of nose gone; ulceration of lip. Note shortening of left index finger from absorption of bone; the nail is still there.

Case with gangosa, showing a nodular eruption on the face; deformity of hand; the right knee was also much enlarged; history of yaws.

places where facilities exist a useful medical examination of servants could be easily carried out. Even if it were considered a hardship by a domestic servant that he should be refused employment because he is a carrier of amœbic dysentery, it would scarcely be regarded as other than a benefit by his prospective employers to be notified of the danger incurred if they engaged him. In fact carriers of diseases like this might well be eliminated from the ranks of house servants and advised to adopt another means of livelihood. There is, I feel sure, a definite need for safeguarding the health of the white residents by some such means as identifiable health certificates for house servants. On the other hand, it is equally incumbent upon us to avoid as far as possible introducing our European diseases to West Africa. It does not appear right that persons suffering from tuberculosis should be admitted into our West African colonies; in view of the extreme susceptibility of the native to this disease, such a procedure can be hardly justified.

THE HEALTH OF THE NATIVES.

Let us now turn from the consideration of the case of the health of the white man in West Africa—which gives just cause for congratulation—to what I consider to-day the real problem of West Africa—that is, the health of the natives. The bush native is regarded by different observers from entirely different points of view according to individual interest.

A Reservoir of Peculiar Diseases.

Now the point of view from which the medical man engaged in research is compelled to see many of the West African natives at home in the bush unfortunately and necessarily leads to his concluding that the bush native in West Africa is a vast reservoir of

or tolerance of disease is acquired at the cost of great personal suffering. Of the rude health commonly attributed to the African natives I have heard much but seen little in the bush during ten years in West Africa. On the other hand, it must be admitted that he stands up to his difficult task of surviving his afflictions with a truly commendable fortitude. As van Loon says of primitive man, "A strange creature, surrounded on all sides by death and sickness, and yet happy and full of laughter."

Provision of Medical Attention.

In the Sierra Leone Protectorate there are 1½ million inhabitants, the great majority of whom live in small villages remote from the railway and large roads and of whom only a small proportion are ever at any time of their lives within reasonable distance of skilled medical attention. The medical officers are in the proportion of 1 to 150,000 of the population, and they are necessarily stationed as a rule at the district headquarters or in military or civil centres. It has long been evident that any adequate provision of medical attention for the 25 million natives of our West African colonies is not feasible if only white or native fully qualified doctors are employed. For this reason there is now in existence a scheme for the establishment of a subordinate medical staff of natives corresponding to the subassistant surgeon of India, who, though not fully qualified, attain in many cases a high standard of efficiency. The opening up of the countries by road and the rapid introduction of motor transport is at the same time enabling existing medical officers to cover more ground in less time, so that in the course of years it may be expected that the more pressing medical and surgical needs of this great population will receive attention. This is an aspect of the results of road construction which His Excellency Sir Joseph Byrne, Governor of Sierra Leone, has kept in the foreground. The new roads will enable motor dispensaries to be used, bringing medical and surgical aid to thousands. While, however, the treatment of individual sufferers from particular diseases is an urgent matter and should be put upon a sound footing as soon as possible, the problem of the ultimate prevention of these diseases is equally urgent, and steps towards this are being undertaken now. The institution of clinics for child and maternal welfare, the inspection and treatment of school-children in larger towns, venereal clinics, and the visiting of homes by trained native health visitors are all evidence of an earnest attempt on the part of the various Governments to bring about improvements in the general health of the native. In this connexion the work of the Royal Sanitary Institute deserves mention. In order to meet a growing demand this Institute has established a special course of tropical hygiene for sanitary inspectors in West Africa, the centres being each of the four West African colonies in rotation, so that each centre will have an examination every four years. Such institutions certainly benefit the town-dwellers, but what of the bush native? As regards the large mass of natives in remote areas, I personally have always been of the opinion that a very great deal could be

Subcutaneous nodule due to *Onchocerca volvulus* near elbow-joint.

Elephantiasis of the scrotum and right inguinal hernia; leucodermatous patches on skin.

Ainhum, which has resulted in the loss of both little toes.

peculiar diseases; that his average physique is poor and that his health is as a rule deplorable; that he is afflicted in immense numbers by appalling diseases and by deformities resulting from them. It may be said of him that considering his poor diet, his unfortunate personal habits, his environment, and his degree of infection with innumerable parasitic and other diseases, he is an outstanding marvel of racial adaptation and survival. But his partial immunity

of the various Governments to bring about improvements in the general health of the native. In this connexion the work of the Royal Sanitary Institute deserves mention. In order to meet a growing demand this Institute has established a special course of tropical hygiene for sanitary inspectors in West Africa, the centres being each of the four West African colonies in rotation, so that each centre will have an examination every four years. Such institutions certainly benefit the town-dwellers, but what of the bush native? As regards the large mass of natives in remote areas, I personally have always been of the opinion that a very great deal could be

done towards the prevention and eradication of disease by education of children and adults also, in simple rules of hygiene and particularly by actual demonstration of how various diseases may be prevented. I have urged that such education should be given in the vernacular and should consist largely of instruction in practical methods of eliminating dangerous mosquitoes, flies, ticks, and snails; teaching as to the dangers of insanitary methods of disposal of excreta and refuse and other obvious instruction. It is my firm conviction that a substantial amount of useful work in preventive medicine can be done by simple village natives who understand no language but their own; I hope to show you some photographs later which illustrate this. The diseases which retard the native, apart altogether from any contact he may have with white people will, for some generations, form an incentive to medical research and sanitary organisations, and will tax them to the utmost.

Goitre: a case from a large endemic area in the Kono district, Protectorate of Sierra Leone.

The native of West Africa so far as I know him is a very amiable, law-abiding person, according to his lights, and in the opinion of many unprejudiced observers his lights are wonderfully good, although they may differ from ours in some particulars. Speaking of what I have seen in Sierra Leone, the opportunities which exist for advance in medical and sanitary work among the natives should not be disturbed owing to any general recalcitrance on principle on the part of the native himself. In fact it appears certain that in the eagerness of his pursuit of health the native of West Africa will be found second to none. Given a remedy capable of producing good effects in any particular disease, effects which are easily observable within a limited time, the natives will flock to you from great distances. I have had, like everyone else, amusing and embarrassing evidence of this when the natives have realised, after much initial reluctance in permitting the treatment, that diseases such as schistosomiasis and yaws could be rapidly ameliorated by injections; at once persons with entirely different diseases came forward asking for injections, and one had to explain that the injection fluid was not a panacea, a statement about which they were frankly incredulous.

Readiness to Receive New Ideas.

A considerable stress is laid by many people upon the effects of native traditional customs on the reception by the natives of the ideas underlying modern sanitation and European treatment. It is rightly pointed out that one must be very careful not to interfere with the tribal customs and that traditional ideas must be respected or trouble will ensue. There is, so far as I can see, from a medical point of view, no necessity whatever to interfere unduly with tribal customs; detrimental customs will in time be given up by the natives themselves

as soon as they become convinced that such customs are inimical to their health and well-being. As a matter of fact no native custom which is frankly brutal and apparently useless, however hallowed it may have been in the past by usage and tradition, is openly tolerated by the Government. Further, it would be difficult to imagine any more subversive change in native customs than the compulsion to pay house tax, yet this revolutionary interference with their traditions has been borne with considerable equanimity, simply because the majority have the common sense to perceive that it is advantageous to them. This same common sense will enable the native very quickly to take advantage of anything which medicine, surgery, and sanitation can do for him. There is, therefore, I believe, no need for those who wish to proceed with the work of ameliorating the health of the natives in the tropics to be deterred unnecessarily by fear of native customs.

A SURVEY OF DISEASE IN SIERRA LEONE.

I have referred to the future task of medical and sanitary workers in the tropics as colossal and I used the word advisedly. It will be my privilege merely to indicate to you the immensity of it in West Africa by reference to a survey of diseases in the Protectorate of Sierra Leone carried out by me at the request of the Government during my last two tours in West Africa. The survey was inaugurated by His Excellency Sir Ransford Slater, now Governor of the Gold Coast, with a view to obtaining some idea of the relative importance of the diseases which affect the native. During two tours I examined as thoroughly as possible samples of the population in all parts of the Protectorate. Over 10,000 natives were examined of both sexes and at all ages, every effort being made to examine all those who were not ill as well as those who were, in any particular village. In order of importance I placed foremost the following diseases: malaria, gonorrhoea, yaws. The two former, serious as they are, are regarded at present by the bush natives rather as natural accompaniments of life than as diseases. Yaws in the frambosial stage is considered a necessary evil; its sequelae, however, such as arthritis, bony deformities, and lesions of the feet are regarded seriously, and gangosa is much dreaded. Both forms of leprosy are of frequent occurrence and are feared, as is elephantiasis; subcutaneous nodules are numerous but are considered by the native as of no importance. Hernia and hydrocele and ulcers they complain of greatly, and these probably cause more serious invaliding than any other conditions. Goitre in certain districts is a serious endemic disease. Diseases of the eyes and ears are fairly frequent, and intestinal diseases such as dysentery and typhoid are also not uncommon. Urinary schistosomiasis is endemic in large areas, but only occasional cases of rectal schistosomiasis

Anæstheticleprosy of many years' duration; the fingers (also toes) lost, self-cured; patient now alert and active.

As a considerable stress is laid by many people upon the effects of native traditional customs on the reception by the natives of the ideas underlying modern sanitation and European treatment. It is rightly pointed out that one must be very careful not to interfere with the tribal customs and that traditional ideas must be respected or trouble will ensue. There is, so far as I can see, from a medical point of view, no necessity whatever to interfere unduly with tribal customs; detrimental customs will in time be given up by the natives themselves

were found. In the following table are shown the numbers found to be affected with a few selected diseases in the Northern Province, part of the survey of the Protectorate of Sierra Leone.

Disease.	Total examined.	Total affected.
Arthritis	2900	143
Dermatitis	2228	1106
Elephantiasis	2904	49
Eye diseases	2194	134
Gangosa	2904	64
Diseases of glands	1953	743
Hernia; hydrocele	2194	408
Leprosy	2904	183
Subcutaneous nodules	2904	306
Ulcers; sinuses; scars	2194	708
Yaws; frambesia	2904	719

The photographs here reproduced give an indication of the variety and serious nature of the diseases which may incapacitate the native of West Africa and prevent his leading a useful life. The figures given must also be taken into account in endeavouring to assess the total amount of personal suffering involved by such diseases.

IMPRESSIONS OF PSYCHIATRY IN AMERICA.*

By EDWARD MAPOTHER, M.D., F.R.C.P. LOND.,
F.R.C.S. ENG.,

MEDICAL SUPERINTENDENT, THE MAUDSLEY HOSPITAL.

In discussing psychiatry in America it is fundamental to appreciate that there is no Federal unity whatever in this matter; there is no less independence and no less difference of maturity between American than between European States. Psychiatric arrangements of all kinds represent 48 entirely separate arrangements. No general law exists and nothing official which is comparable to the Board of Control as a nation-wide and standardising agency. The same is true as regards the Province of Canada. The nearest approaches to any unifying organisations are the National Committees of Mental Hygiene financed from voluntary sources which endeavour by propaganda everywhere to raise the standards of care, treatment, education, and research. Though unofficial these committees have been asked to undertake surveys of the situation and the requirements in various States and Provinces, and in some ways such unofficial bodies if of good repute have advantages over organisations like the Board of Control. Their view of situations may be more comprehensive because they more readily get access to places out of the official orbit such as schools. Just because their statements have no necessary consequences they can express their real opinions without deference to the political and financial situation of the moment. After the passage of the Mental Treatment Bill, an organisation effectively corresponding to the National Committees of Mental Hygiene in America and Canada will be more badly wanted than ever before.

The purpose of my visit to America was not to see a truly representative sample in a critical spirit. I was admittedly out to see all that was best and most interesting—the “high spots” as they are called locally. Therefore any generalisations which I may venture apply only to what I saw, and for the most part to psychiatry in America at its best. Only in special connexions shall I refer to what seem backward arrangements. I shall make no criticism of American arrangements that is not really a quotation of expert opinion there. I want especially to

emphasise features of American psychiatry that are topical. The Mental Treatment Bill seems likely to be this generation's contribution to progress or reaction, and it has now reached a fairly definite form. There are many points about American arrangements which throw a flood of light on the situation foreshadowed by the Bill, but I know of no evidence that American arrangements were considered before drafting it. In the parts of America that I visited I saw an amount of psychiatric research in progress that could not possibly be equalled in a similar tour of Great Britain. I do not profess to estimate the ultimate importance of anything I saw. Results that really make a difference are, of course, the product of a very few minds in each generation, but in opportunities for solid steady contribution to knowledge America is incomparably ahead. The view-points in research represent every school, and all extremes of course, but most of it is perfectly sane. I met one thinker of the “hard-boiled” materialist school who proposed to oust the term “emotion” from psychiatry in favour of the phrase “reaction through the diencephalon.” On the other hand, a psycho-analyst conducting research on treatment of dementia præcox had painted the walls of his patients' rooms yellowish brown, as a substitute satisfaction for the anal erotism which was supposed to be fundamental. But neither of these was representative.

The Differences between American and British Psychiatry.

It appeared to me that the outstanding differences of psychiatry in America included four factors, and one main resultant. The four factors were as follows:—

1. The enormously rapid growth of population.
 2. The extent to which official provisions at public expense are supplemented by bequests, donations, and above all from such sources as the Commonwealth Fund and the Rockefeller Foundation.
 3. The degree in which the American psychiatrist is master in his own house—a degree which is unthinkable in our lawyer-ridden land.
 4. The far wider diffusion and the much higher level of psychiatric education of all kinds in America.
- The main resultant of these factors is the greater tendency in America to look upon the existence of mental disorder as a problem to be solved rather than a burden to be borne.

Rapid Growth of Population.—This means that institutional provisions for mental disorder tend always to be in arrears; the results are good, bad and doubtful. In general it may be said that the shortage reduces stereotypy. It affords frequent opportunity for embodiment of new thought by the addition of new institutions and of new features to old ones. It promotes a tendency to try legitimate substitutes for institutional treatment, and even to invest money in attempts at prevention and cure. Among the many excellent things that have largely resulted from institutional shortage are the extramural activities of the State hospitals and State schools. Clinics based on these institutions deal largely with cases of mental disorder and mental defect, who are able to stay at large under supervision, either after a period in a State hospital or without this preliminary.

Among the bad results of institutional shortage are:—

- (a) Overcrowding almost everywhere.
- (b) The need in places to treat some patients with transient and incipient psychosis in the city gaol.
- (c) Discharge of patients in some places by lay and legal authority, in disregard of the medical superintendent's opinion, to make room for others.
- (d) A tendency in places to reserve institutions for the worst and most antisocial cases of both mental disorder and mental deficiency.
- (e) Delay in providing public hospitals for minor cases of both conditions. This is usually rationalised by a general claim to have discovered the fallacy of early treatment.

* A paper read at the Section of Psychiatry, Royal Society of Medicine, on April 8th.

In Massachusetts—the most progressive State—mental deficiency institutions are unclassified. Massachusetts is interesting, and at least logical, in that it justifies the mixed institutions for mental defectives by the very same arguments that in London are thought to justify mixed mental hospitals, but which do not prevent mental deficiency institutions here from being graded.

One of the doubtful tendencies due to institutional shortage is the very high proportion of cases of both mental deficiency and insanity which are on parole with friends—e.g., nearly 5000 out of the 45,000 insane for whom New York State is responsible at any given time. Doubts of the consequence of this probation from the eugenic standpoint, even when it is coupled with extramural supervision, are largely responsible for the legislation which in 12 States combines sterilisation with probation and supervision.

Donations.—Much is due to the enlightenment with which this generosity has been applied; the wise use of it is the ideal corrective for the politicians' tendency to think financially with reference to the next election rather than the next generation. In most places State provision has perhaps necessarily focused on the worst cases of mental disorder and mental defect. The Commonwealth Fund and the Rockefeller Foundation, collaborating largely with the National Committees of Mental Hygiene of America and of Canada, have concentrated on a triple programme.

1. Upon promotion of the advanced training of psychiatrists and of research by the grant of fellowships at centres like the Phipps Psychiatric Clinic and at the Boston Psychopathic Hospital.

2. Upon a programme of propaganda and of prophylaxis and early treatment of minor divergences through out-patient clinics. One of the most striking movements is the provision of mental hygiene facilities at the universities as part of the health service which is a recognised provision for undergraduates.

3. Upon the Child Guidance movement which owes its growth, though not its birth, to private generosity. There can really be no doubt about its influence, in reducing unhappiness during childhood, and in averting the anomalies of character that are continuous with definite neurosis and with criminality.

The Foundations in America have always observed the wise principle that the rôle of private endowment is to give a start to promising novelties and to insist that when a given service has proved its case as a need of the community, then the time has come for the community to provide that service and to finance it locally whether by taxation or by voluntary contributions. It may be rank heresy, but the policy of the American Foundations leaves me wondering whether progress might not be faster in this country if private generosity could be directed more to new ventures and less to established institutions (such as voluntary hospitals without medical schools to justify them). These would inevitably exist as a public service if not privately supported. Despite all that psychiatry owes to philanthropy in America, I want to stress the fact that our national shortage of millionaires is not a complete excuse for the gap between the best State systems in America and the best in England. Anyone who doubts the gap should make a careful study of the whole system under the Department of Mental Diseases for the State of Massachusetts—including its provision for research. This system owes comparatively little to private benefactions. The Institute of Juvenile Research in Chicago is also a splendid organisation for child psychiatry, supported wholly by the State of Illinois.

The Emancipation of the Psychiatrist.—This replacement of the static mind of the lawyer by expert knowledge, and the experimental spirit in control, is the great guarantee of the future in America. This transfer of control is most complete in the most highly organised and most progressive States; such

as Massachusetts and New York, and all tendency to question it—even by lawyers—seems to be over. Before detailing how the psychiatrist in America has secured the management of what are indisputably his own affairs—i.e., arrangements for the neurotic and psychotic—I may just refer to the way in which he is there getting a voice in dealing with another form of mental disorder—viz., criminality. In Detroit there is attached to the Recorder's Court (handling nearly 10,000 felonies and 30,000 miscellaneous a year) a complete psychopathic clinic with two psychiatrists and a group of social workers and psychologists. To this clinic about 1000 cases per annum are referred—felonies and misdemeanours in about the ratio of their occurrence. The reference may be:—

(a) Before trial—for opinion as to responsibility.

(b) After verdict and before sentence, as to whether this should be, on the one hand, commitment to prison or reformatory and for how long, or, on the other probation with supervision.

(c) For guidance as to problems arising while on probation.

The court follows the clinic's recommendation in nearly 90 per cent. of reference cases. When there is any difference the court almost always takes a less severe course than that recommended by the psychiatrist. This is a good answer to the view that asking the alienist means coddling the criminal. Ninety per cent. of cases in which probation is advised by the psychiatrist keep straight. The general usefulness of such reference is shown by the fact that even offences in connexion with driving motor-cars are found to have a correlation with mental disorder; I rejoice to say they are not pathognomonic. Similar arrangements exist at Cleveland, Ohio. Here the psychiatrist was not a whole-time officer of the court when I visited, but his appointment was being considered, since so large a proportion of all cases coming before the court were referred to him. In the two most advanced States of America, the Commissioner at the head of the department of correction is a psychiatrist. This department is responsible under the Governor for all penal arrangements, as is the Home Office in England. In the State of Maryland the Commissioner for Mental Diseases has authority to transfer any person from prison to a mental hospital, which constitutes an absolute power to adjust any punishment except that of death. Nobody seems inclined to question these arrangements.

Arrangements for Prevention and Care of Neuroses and Psychoses.

The arrangements for the future in England which will follow the Mental Treatment Bill are as follows: Hitherto the medical element of the Board of Control has been equal to the legal and lay. Hereafter it is only secure that one of the "Big Five," who are to settle all policy, shall be a doctor. A proposal that he should necessarily be a psychiatrist was negatived by the Select Committee of the House of Commons. The position of the only other doctors connected with this new Board of Control was neatly summarised by the statement that they were to be the servants of alternatively the hands and eyes of the "Big Five"—who presumably will combine the functions of brain and mouth. With this may be compared the position in the most advanced States of America—Massachusetts and New York. Here all psychiatric provision and supervision by the State is entirely in the hands of a State Department. There is no triplication of function, as hitherto, between Board of Control, county council, and guardians, nor even duplication, as now, between Local Authority and Board of Control. There is a simplification which may be roughly compared to what would exist if all public provisions for psychiatry had to the Board of Control the relation which Rampton now has. In other words, the State Department is responsible for everything in respect of public institutions, and is responsible for all rules, supervision and management, obtaining from the

legislature the necessary funds for provision and for maintenance. In private institutions it is responsible for rules and supervision. Over this Department for Mental Diseases is a permanent head—the Commissioner—with powers far exceeding in every way those of the Board of Control, having direct access to the Governor of the State without intervention of any Minister or other layman, lawyer, or politician, and through the Governor, access to the legislature. It is definitely laid down by law that the Commissioner shall be not only a doctor but a psychiatrist, with at least five years' institutional experience. Though nominally his tenure may cease with that of government by one party, in practice it is permanent. The progressive States of America have done with making political appointments to such posts, and with attempts to influence the policy of psychiatrists by political considerations. Such States have also discarded the system whereby the senior civil servant desiring such promotion is thought fit to direct the activities of the State in respect of psychiatry when a vacancy occurs, regardless of previous knowledge or experience of the subject. On the best authority I understand that in practice the Governor and the Legislature in progressive American States consider that their province is limited to deciding how much can be appropriated for new projects of the department, and whether the general financial situation permits of finding the money needed for the proposals advocated by the Commissioner of Mental Diseases. Apparently detail is left to him entirely, and even the order of priority of his proposals. With this may be compared, by those with time to spare, the official reports of the discussion upon the Mental Treatment Bill. America has apparently lost our English faith in settlement of technical detail by the inexpert. Within the Department of Mental Diseases in Massachusetts, there is no lawyer, except one concerned in recovery of contributions due from relatives of patients. There is no layman, except the woman at the head of the Social Service Division. The Assistant Commissioners or the heads of all other divisions are psychiatrists.

Of these the Commissioner is chief, with almost autocratic powers in reserve. His immediate subordinates—each in charge of a division of the department—are what we should call in England deputy medical superintendents, seconded to headquarters. On occurrence of a vacancy as medical superintendent, one of the assistant Commissioners goes back to run the mental hospital, and another deputy superintendent comes up to headquarters. Every month in Boston a dinner is held (subject to the 18th Amendment), and attended by all the superintendents and all the assistant Commissioners, with the Commissioner in the chair. At this, free discussion of official matters is encouraged. The whole scheme seems ideally adapted to reduce to a minimum the gap between regulations and reason constituting the headquarters spirit with which so many of us first became familiar in the war.

Commitment Law.

This varies in different States from the extreme of legalism to the fully medical conception. In certain States it is still, or recently was, indispensable that the alleged insane person should be tried in open court before a judge and jury, and should plead guilty or not guilty to the charge of insanity. Slight modifications of this are common. It is also common that upon a writ of habeas corpus an already certified person has to be produced in court for the question of his insanity to be settled by a jury, who may disregard the medical superintendent's opinion. This is the situation in Washington, the American home of the politician and the lawyer.

When I was there a lawyer had just been shot by a lunatic whose discharge he had obtained a year before through such a writ of habeas corpus, in spite of the fact that the man had been certified after a previous homicide, and despite the fact that Dr. White, of St. Elizabeth's Hospital, had opposed the

discharge. The effect of this piece of poetic justice had not yet become evident.

On the other hand advanced medical opinion in America is moving steadily in favour of total abolition of the judicial authority in commitment procedure. It is reasonably pointed out that there is no more reason to anticipate ignorance, bad faith, or lack of reasonable care in the case of a doctor than of a magistrate, and that if, of two certificates required, one must be given by an expert and approved psychiatrist, then the patient's interests are far more adequately protected than by any magistrate. In Maryland complete dispensation with the judicial order is an established fact. A patient can be committed for permanent (not mere temporary) detention on the certificate of two medical practitioners. It is not even provided, I believe, that either should be expert and approved. But there is an onus on the Commissioner to see the patient either at an ordinary or special visit. The system works perfectly well. Abuse would involve ignorance, neglect, or conspiracy of the two certifying doctors, the superintendent and the Commissioner, and naturally does not occur. Further, the system works well from the doctor's standpoint. As a rule in Maryland the same situation exists as in England with private cases. Even though still insane, patients are usually discharged upon application of relatives who will vouch for care and control—except in rare instances of clear suicidal or homicidal propensity. Actions for illegal commitment are no commoner than elsewhere and practically never successful.

Psychiatric Education.

The education of the public has reached a point where the man and woman in the street know about the existence of mental hygiene services and are prepared to utilise these for their children and even for themselves. One of the most interesting educational projects in America—a counterblast to excessive specialism—is the foundation of the Institute of Human Relations at Yale. Here it is intended that, as the preliminary of their professional training, the future doctor, lawyer, clergyman, and others, whose business is the handling of people, shall get a common grounding in at least the elements of biology, physiology, and psychology, including among the practical derivatives of psychology, sociology and some psychiatry. It is intended to make of this psychobiology an essential common ground-work, almost as we build on a foundation of dead languages.

As to pregraduate medical education in psychiatry there is no university or medical school in this country which approaches in thoroughness that which is universal in at least ten American universities. Comprehensive courses are given in each of four years of medical training—a real grounding in medical psychology and psychopathology. The students are taught clinical psychiatry by lectures and demonstrations, and personal study of patients by allocation of definite cases of neurosis and psychosis, but above all by direction of attention to the psychiatric aspect of those illnesses seen in the ordinary wards and clinics. In Columbia as much time is devoted to the study of psychiatry as to each of the other major subjects—medicine, surgery, and gynaecology. Since quite similar situations exist in Germany and Holland and generally in progressive European countries, it seems doubtful whether the thinly veiled pride which the run of English practitioners take in their ignorance of psychiatry is really referable to our genius for practicality. There has hitherto been no diploma in psychological medicine in America, but I know that Prof. Adolf Meyer is interested in the institution of one—possibly of one in each State with equal standards.

For acquisition of technique from those actively engaged in various branches of research, and for really advanced teaching, American psychiatrists have of late years mainly gone to Vienna—except in respect of neurology, for which all say that the

National Hospital, Queen-square, is the best centre in Europe. In view of the staffing and facilities which will be available in the three psychiatric institutes which are to open shortly—those in New York connected with Columbia and Cornell Universities and that at Philadelphia, the current may well flow the other way soon.

In America, most of the ideals held up by the Committee appointed by the Board of Control on the training of mental nurses are realities. The State of New York is enforcing as a preliminary requisite of nursing a high school education until 18. The inclusion of general training in the mental nurse's course and, conversely, the mental training of both pre-graduate and post-graduate general nurses are commonplace.

My impression of the general differences representing the resultant of the four factors which I have emphasised was as follows: As to psychiatry, America is interested chiefly in development, England in maintenance. American attention is fixed mainly on what will be and English on what has been. American arrangements often seem unfinished, like everything that is growing, occasionally crude enough to offer scope to the scoffer. But efforts limited to maintaining the standards of the past in psychiatry, as in everything, are apt to fail, and fixation to be followed by regression. In actual structure and maintenance of those types of public institutions which exist in England and of amenities for patients, I doubt whether America has much that clearly outstrips the best in England. The most striking places that I saw were Bloomingdale, near New York—what we should call a registered hospital—and a hospital at Northampton, Massachusetts, run by the Veteran's Bureau (or Ministry of Pensions). Comparing the general maintenance cost of institutions in the States of New York or of Massachusetts with the cost in London, there is little evidence of better maintenance in America. Nor could I find that the public attitude to in-patient treatment there was different.

Voluntary Patients.

Owing to the wide extramural activities of American State Hospitals, these are much less suspected than their equivalents in England. But though provision for treatment of voluntary patients in the State hospitals of Massachusetts and New York has existed for many years, the public response is negligible.

In Massachusetts there are practically no voluntary boarders. In New York, of 45,000 State-aided patients, 652 were voluntary. In New York hospitals in 1927 there were 11,500 admissions. Of these, 5 per cent. were voluntary. Of this 5 per cent., one-half were recurrent; of the other half, the great majority would otherwise have been there under certificate, while most of the minority belonged to the hoboe class. This is an illuminating commentary on the Mental Treatment Bill, Clauses 1 to 4, especially when coupled with reassurances given by the Minister of Health to anxious representatives of local authorities that no new expenditure or new building need be feared—that what is intended is treatment of the same types in the same buildings by the same staff with different formalities.

It has been said that if private patients in large numbers will voluntarily enter such an institution as the Retreat, where some other patients are certified, then the poorer classes will resort to the county mental hospitals as voluntary patients when this is permitted. American experience shows this to be an utterly false analogy. Such institutions as Bloomingdale have 70 per cent. of voluntary admissions nowadays, but the State hospitals have practically none in any real sense. In fact, owing to widespread possession of means enough to pay for a time the cost of treatment outside a State hospital, these American registered hospitals are rapidly becoming the places where all but the very poor are treated for incipient and transient psychoses. The

actual position is that public provision for the voluntary case by the State is as yet almost as defective in America as in England. The only wholly voluntary institution, comparable to the Maudsley, is the Phipps Psychiatric Clinic. This is splendid, but it is neither State-supported nor does it provide in any considerable measure for the poor. Both these remarks apply equally, I believe, to the forthcoming Psychiatric Clinic at Philadelphia and that connected with Cornell University, New York. The other, connected with Columbia University and located in the medical centre of New York, may be more analogous to the Maudsley. The out-patient departments of the Phipps, the Boston Psychopathic, and Cornell Clinic, New York, were the most striking. The latter is run in a general hospital like various such departments in London, but on a paying basis more like that of the Tavistock Clinic, and is well organised and flourishing.

Hospitals undertaking initial observation and treatment of psychosis under temporary treatment orders are usually managed by the city authorities, whilst hospitals for more prolonged care are maintained by the State. The Boston Psychopathic Hospital, closely connected with Harvard University by the State of Massachusetts, is exceptional in this as in all else. But splendid as it is, and negligible as are the formalities attending commitment there, there were only 58 voluntary admissions out of 1906 in 1928. This suggests how little importance the public will attach to any difference about admission under Clause 5 of the Mental Treatment Bill. The reduction of formalities is far greater in regard to treatment to Boston Psychopathic than under Clause 5.

The City Psychopathic Hospitals in many cases have university connexions and useful functions in teaching. From the standpoint of the patient I gathered that their repute was not high. Of the Belle-vue in New York it is fairer not to speak, since it has been decided to abandon and replace the psychiatric part of this. Others that I saw seem better than most London observation wards, but far from ideal. They were mostly constructed of glass, metal, tiles, and concrete in what has been called the neo-laboratorial style of architecture. The ease with which they can be washed down with a hose doubtless admirably adapts them to their special purpose, but it is difficult to reconcile with a home-like atmosphere.

It is not better buildings or maintenance that constitute the real difference of American psychiatry. The difference depends upon the medical spirit dominating it, and consequent pre-occupation with treatment and research. An outstanding feature of all American institutions is the number of doctors. St. Elizabeth's Hospital, Washington, with over 4000 patients, has 40 doctors, and Dr. White reckons that the right proportion is one doctor per 100 patients. Elsewhere the proportion accepted is one per 150 with a special allowance in proportion to admissions. This ratio would just double the number of medical officers in all London hospitals. In reality the amount of medical work which is possible is much greater owing to reduction of clerical work by the use of dictaphones and stenographers. Scientific work is encouraged by establishment, just below the superintendency, of three equal positions—that of administrative assistant, clinical director, and pathologist—each providing a satisfactory career. The medical superintendents of most of the notable State hospitals have teaching positions, and all the junior staff are stimulated—not forbidden—to form connexions with other hospitals outside. In spite of this, in America, as in England, there is difficulty in getting doctors of the best quality to enter psychiatry. This exists even in the schools where teaching is best; staff vacancies are not readily filled from the universities with which the psychiatric clinics are connected, and candidates have to be sought outside. To some extent the difficulty is declining as the repute of psychiatry grows. But one difficulty which remains is creditable to the moderation of the medical profession in view of its

control of the situation. Though the numbers of medical officers are high, salaries are low; they seemed on the average to be little higher than in England. Considering the general scale of American incomes, I think this clearly means a relatively lower financial status. It is a pity if this should prevent advantage being taken of the splendid opportunities which exist.

Judged by the standard of recent achievement, psychiatry in America is probably, on the whole, the equal of that in any country of the world, but it is very uneven in all respects. Hardly anywhere is everything all that one might fancy, but somewhere every improvement that we are merely talking about is in working order, serving as the little leaven that leaveneth the whole mass. America, like every country, has its cranks, but the people who are directing the development of its psychiatry are not that. They have the national readiness to try anything once, but to me they seem to be neither credulous nor given to making claims. In fact they seemed full of the "enthusiasm without illusions" that is the true scientific spirit. I have had glimpses of the psychiatry of ten European countries. I think the future is more secure in America than in any other country because it is rooted in the four factors of which I spoke. Lastly, in view of the respective estimates of British and American psychiatry prevalent outside the two countries, there is little room for that complacent tolerance towards the enthusiasms and efforts of others which is apt to pass for humorous wisdom in England, and seems so maddening to all the other nations of the earth. Those who can may hope that the leadership which has produced the Mental Treatment Bill as it is will somehow secure the expensive supplementary arrangements which alone will make it more than a change in formalities. Others may hope that, if an opportunity for real progress is given to the next generation, it may be based on knowledge of arrangements actually working elsewhere, rather than on lawyers' bogeys subtly evolved from the inner consciousness.

THE RELATION OF ACETO-ACETIC ACID TO DIABETIC COMA, AND THE CAUSE OF DEATH.

By E. C. DODDS, M.V.O., M.D., PH.D. LOND.

COURTAULD PROFESSOR OF BIOCHEMISTRY, UNIVERSITY
OF LONDON;

AND

J. D. ROBERTSON, M.B., D.P.H. LOND.

ASSISTANT CHEMICAL PATHOLOGIST, MIDDLESEX HOSPITAL.

(From the Courtauld Institute of Biochemistry,
Middlesex Hospital.)

THIS communication is concerned mainly with two aspects of diabetic coma: firstly, the factors leading to the establishment of the condition; and secondly, those responsible for death in coma.

Cause of Diabetic Coma.—Amongst the views expressed by various writers on this subject, those ascribing the condition to ketosis or acidosis occupy by far the most important position. Supporters of the acidosis theory maintain that coma is due to the production of acids following the faulty metabolism of fats, and that the accumulation of such acids in the blood leads to a depletion of the alkali reserve. This value sinks from a normal of some 52–75 c.cm. CO₂ per cent. to 20 c.cm. or lower in the majority of patients with diabetic coma, and the relative constancy of this finding has led many observers to regard a depleted alkali reserve and diabetic coma as being causally related. Whilst it is well known that acidosis will produce an increase in the depth of respiration, it is equally well realised that acidosis

occurring in non-diabetic conditions such as prolonged vomiting and the terminal stages of nephritis, will not produce the symptom-complex of diabetic coma. The frequently recorded observation that diabetic coma can occur with either a normal or only slightly depleted alkali reserve, forms another argument against the acidosis theory.

The ketosis theory ascribes the onset of coma to the increasing accumulation of ketone bodies, such as aceto-acetic acid and β -hydroxybutyric acid, in the circulation. The evidence in favour of this theory is two-fold: firstly, the concentration of acetone bodies in the blood greatly increases in comatose and pre-comatose conditions; secondly, the careful animal experiments of Hurlley and Trevan¹ showed that if aceto-acetic ester is injected intravenously into cats the amplitude and frequency of respiration is greatly increased. As a result of these observations these workers suggested that the onset of coma could be explained by the increase of aceto-acetic acid in the blood. They attributed the symptoms to the presence of the enol group in aceto-acetic acid and showed that other substances containing this group also produced an increase in the rate and amplitude of respiration. The only determinations of aceto-acetic acid in the blood found in the literature are those of Marriott,² Geelmuyden,³ and Kennaway.⁴ The latter investigated blood from diabetic patients which, with one exception, had been obtained at autopsy. He supported the view propounded by Hurlley and Trevan. It is interesting to note that his observations record concentrations very much higher than those about to be described. Kennaway also suggested that a continuous series of investigations on patients during and after coma would be necessary before the theory could be accepted in its entirety, and we have followed out this suggestion.

Since no answer has been given to these problems it was thought that an investigation of diabetic coma from the point of view of the variation in both the aceto-acetic acid content of the blood and in the alkali reserve would be of interest.

Observations on Patients.—The following account is based on a study of seven cases. Of these, four were in definite diabetic coma and showed the classical symptoms of unconsciousness with Kussmaul respiration, subnormal temperature, and reduced intracellular tension. Two cases were in a pre-comatose state and were severe diabetics who developed gastro-intestinal symptoms, subnormal temperatures, and weakness. They were sufficiently well to walk to hospital, and being experienced diabetics realised that their condition was urgent. The seventh patient was suffering from inoperable carcinoma of the breast with secondary deposits. Severe diabetes was also present, requiring at least 50 units of insulin a day for the control of a very restricted diet. In view of the terminal nature of the malignant disease it was decided to impose no dietetic restrictions or treatment with insulin. This series of cases presented two aspects of diabetes; the first six were severe cases in whom every attempt was made to control the condition, whilst in the seventh case, also a severe diabetic, no such attempt was feasible.

Methods of Investigation.—The alkali reserve of the blood was estimated by the method of Van Slyke,⁵ great care being taken to ensure uniformity in the determinations. Thus, saturation of the specimen with CO₂ was performed by a gas mixture containing 5.5 per cent. CO₂ in air in a cylinder. The acetone bodies in the blood were estimated by the method of Behre and Benedict⁷ in the form of volatile and non-volatile acetone bodies. Since the blood contains little or no acetone⁸ these estimations correspond respectively to aceto-acetic acid and β -hydroxybutyric acid.

Results: Ketosis.—In Table I. will be found a record of the aceto-acetic and β -hydroxybutyric acids in the blood of the seven cases referred to above. The observations quoted were the highest figures found during the course of the condition. It will be remembered that Case 7 was the patient

with inoperable malignant disease. Despite the fact that insulin administration was discontinued this patient did not go into coma. The diet was liberal and the patient was allowed to eat fats freely. The blood-sugar rose to 500 mg. per 100 c.cm. and the urinary output of sugar reached 11.7 mg. per 100 c.cm., whilst the daily excretion of urine varied from 2000 to

TABLE I.

Case.	Condition.	Aceto-acetic acid.	β -hydroxybutyric acid.
		mg. per 100 c.cm.	
1	Coma.	27.0	78.8
2	"	24.5	44.4
3	"	43.5	61.5
4	"	25.0	40.0
5	Pre-comatose.	11.5	33.0
6	"	40.5	34.3
7	Non-comatose.	35.3	133.0

2000 c.cm. This patient showed no symptoms of coma, the alkali reserve averaged 65 c.cm. CO_2 per cent., and on the day before death was 63 c.cm.

An inspection of the table reveals the interesting fact that the amount of aceto-acetic acid in the blood bears no relationship to the clinical state. Thus, one of the patients in the pre-comatose group possessed a higher concentration of aceto-acetic acid than three of the patients in the comatose group, whilst the seventh patient had a higher figure than three of the patients in coma. It is admitted by most workers that β -hydroxybutyric acid bears no relationship to the aetiology of coma, and the results in the table bear out this view.

TABLE II.

Case.	Alkali reserve : c.cm. CO_2 per cent.	Case.	Alkali reserve : c.cm. CO_2 per cent.
1	8	8	42
2	13	9	40
3	24	10	36
4	14	11	29

Acidosis.—Turning now to the acidosis theory, observations on four of the above patients together with four from a different series of cases of diabetic coma are recorded, and in Table II. will be found the lowest alkali reserve content of the blood. It will be seen that the figures are very variable indeed, ranging from 8 to 42 c.cm. These observations confirm the fact that there is no constant relationship between reduction of the alkali reserve and diabetic coma.

In cases of non-diabetic acidosis, such as that occurring in uræmia, or persistent vomiting, the alkali reserve may be reduced to as low a figure as 12 c.cm., as happened in a patient examined by us, without the patient losing consciousness. To conclude,

TABLE III. (Case 3).

Date in 1929.	Time.	Aceto- acetic acid.	β -hydroxy- butyric acid.	Alkali reserve : c.cm. CO_2 %.
		mg. per 100 c.cm.		
23/12.	9.0 a.m.	43.5	40.0	24
	12.30 p.m.	43.5	64.5	24.5
	3.0 p.m.	41.7	64.5	32.5
	6.0 p.m.	18.2	17.7	47
	10.0 p.m.	10.9	5.0	53
29/12.	2.0 a.m.	2.4	25.0	53

2.30 a.m. death.

therefore, a patient may be in diabetic coma with either a high or a low alkali reserve, and, alternatively, a non-diabetic patient may have a very low alkali reserve and still be conscious.

In order to follow the course of events in diabetic coma, blood analyses were performed at three-hourly intervals until recovery or death took place. In Table III. are recorded the variations in the acetone

bodies and alkali reserve in a fatal case of diabetic coma.

It will be seen that the aceto-acetic acid content of the blood fell steadily until the fatal termination. The alkali reserve rose, and it would appear that neither of these values bears any relationship to the cause of death. It is also interesting to note that this patient only received half a drachm of sodium bicarbonate and yet the alkali reserve rose steadily until death supervened. A post-mortem examination failed to reveal any complications.

Closely parallel figures to those in this table are found in Table IV., the analyses in this case being performed on a patient who recovered. These observations seem to show that neither the acidosis nor ketosis theory adequately explains the cause of diabetic coma.

In addition to the fact that the concentration of aceto-acetic acid in this patient's blood when in fully established coma was considerably below that of our

TABLE IV.

Date in 1930.	Time.	Aceto- acetic acid.	β -hydroxy- butyric acid.	Alkali reserve : c.cm. CO_2 %.
		mg. per 100 c.cm.		
22/3.	10.45 a.m.	25	40	14
	12 noon.	Recovered	consciousness.	
	3.0 p.m.	40	35	47
	10.30 p.m.	26.3	21.6	63
23/3.	10.30 a.m.	33.3	30	55
24/3.	10.30 a.m.	20	30.8	51

non-comatose patients, it increased after the patient recovered consciousness. This unexpected observation was confirmed in subsequent cases, and therefore provides another argument against the enol theory.

The Cause of Death in Diabetic Coma.

Three possible causes of death in cases of uncomplicated diabetic coma may be put forward: (1) advancing coma—i.e., acidosis or ketosis according to the theory supported; (2) nitrogen retention; (3) circulatory failure.

In the previous pages it has been shown that even with appropriate treatment causing reduction of the blood-sugar and a concomitant rise in the alkali reserve the patient may still die. Nitrogen retention occurs in some cases of diabetic coma but appears to bear little relationship to the question of death or recovery. Cases of combined uræmic and diabetic coma are, of course, excepted from this series. The last theory—namely, that of circulatory failure—must be adopted if only by a process of elimination. It has received considerable support from such writers as Joslin, and more recently Graham* and one of us (E. C. D.).¹² A constant finding in fatal cases described by previous writers and also observed in this institution is a persistently falling blood pressure. In the last three cases the blood pressure was unobtainable at the brachial artery, and was certainly below 60 mm. Hg systolic. Another invariable symptom is collapse of the veins, making it exceedingly difficult to obtain blood by the usual routes. Some workers (Graham, Kennedy) have described alterations in the appearance of the blood removed from such patients and have remarked on the difficulty of obtaining it by a syringe. They describe it as being sticky. This phenomenon has been attributed to the concentration of the blood and is associated frequently with a raised hæmoglobin content. In order to investigate this problem, the variations in the hæmoglobin and total solids content of the blood were studied. As this proved more elaborate than was originally expected it will form the subject of a future communication, and it will here suffice to refer to the findings very briefly.

Observations on a series of patients in diabetic coma showed that the hæmoglobin content as estimated by Newcomer's method did not rise above the normal figure of about 15 g. per 100 c.cm., whilst the total solids

yielded similar results—i.e., they did not rise above the highest normal figure of 23 g. per 100 g. of blood. If the patient recovered from coma it was found that the hæmoglobin content fell rapidly, as also did the total solids. It appears, therefore, that although there is little evidence in this recent series of concentration, yet there is definite evidence of dilution following recovery. In support of this it was also observed that the veins became fuller when the patient recovered, and one in whom there were no veins palpable or visible at the elbow, and from whom the blood had to be collected by arterial puncture when in coma, developed normal and full veins on recovering consciousness.

Many observers (Bock, Field, and Adair,¹¹ Rosenbloom,¹² McCaskey,¹³ Starr and Fitz¹⁴) have recorded the death of patients in coma with no acetone bodies in the urine. This has led them to postulate the production of an unknown acid body. It would appear that the phenomenon might be explained on the line of circulatory failure, since in Case 3 treatment had reduced the acetone bodies to within normal limits and had raised the alkali reserve, yet death supervened from circulatory failure.

With regard to the alteration in the composition of the blood in coma, it is perhaps permissible to digress from the chemical aspect and mention the leucocytosis which always occurs in diabetic coma. This is not described in the majority of text-books and in our experience is very little known. It is described by Allen¹⁵ and Joslin.¹⁶ In all cases examined by us there was a definite leucocytosis with over 20,000 white cells per c.mm. It seems, therefore, that this should be borne in mind in the differential diagnosis of any condition giving rise to leucocytosis.

Summary.

1. A study of (a) the aceto-acetic acid and (b) the alkali reserve content of the blood in patients in diabetic coma failed to support the theories of ketosis and acidosis respectively as a cause of this condition. Thus, in many cases non-comatose diabetic patients were found to have a higher aceto-acetic acid content than the comatose patients, and it was found impossible to correlate the blood analyses with the clinical condition of the patient.

2. On recovery from coma it was found that the aceto-acetic acid content rose, thereby further indicating that the enol theory of diabetic coma is improbable.

3. In the fatal cases it was found that death was preceded by a persistently falling blood pressure, and the importance of circulatory failure is indicated.

4. The occurrence of leucocytosis in coma is confirmed.

We have to thank Dr. G. E. Beaumont, Dr. G. E. S. Ward, and Dr. D. E. Bedford for giving us permission to examine their patients.

WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF;

AND

LAMBERT ROGERS, M.Sc. WALES, F.R.C.S. EDIN.,
F.A.C.S.,

SENIOR ASSISTANT IN THE SURGICAL UNIT OF THE SCHOOL.

IN THE LANCET of Feb. 4th, 1928, we recorded six cases of tumours of the spinal cord which had been under our care within one year. The present communication deals with points of special interest presented by three additional cases. Two were women, aged 42 (Case 1) and 24 (Case 3) respectively, and one a man, aged 32 (Case 2). There was no occupational incidence, nor was there a history of injury preceding the onset of symptoms in any of the cases. In Cases 1 and 2 the tumour was situated in the thoracic region of the cord, in Case 3 in the cervical region. This last case was of special interest because a swelling had appeared in the side of the neck about six months before spinal symptoms became manifest and led us to make a tentative diagnosis of a "dumb-bell tumour"—i.e., a tumour having one part outside and another part inside the spinal canal, the parts being joined by an isthmus passing through an intervertebral foramen. This diagnosis proved ultimately to be correct.

A feeling of coldness or numbness was one of the earliest symptoms in each of the cases. In the cervical case this symptom was first referred to the right hand, in the other two cases (thoracic) it was referred to one or both lower limbs. One thoracic case had, in addition, a tingling sensation in both feet as an early symptom, and the other had a sense of constriction in the lower part of one thigh. The cervical case developed "tingling" in both hands about four months after the onset of the numb feeling. In this case, also, loss of power in the right hand and arm quickly followed the initial feelings of numbness, and within four months the patient was quite unable to use this limb. In the two thoracic cases slight stiffness developed in one leg, associated with some dragging of the foot, three months after the initial symptoms in one case, and six months after in the other. All three cases had suffered from a "girdle" sensation at some period in their course but not at the beginning. This sensation was not one of pain but rather of constriction—like a "tight band" around the body. Only one (Case 1) exhibited root pains and these were not constant and only appeared late—about ten months after the onset of other symptoms. No tenderness over any of the vertebrae was made out and no abnormality of the spine was found.

The spinal level diagnosis was arrived at from a careful study of the physical signs, but in all cases confirmation was sought, prior to operation, by lipiodol injection into the spinal subarachnoid space by puncture of the cisterna magna as described in our previous paper. Before the lipiodol injection the spine was X rayed to exclude any lesion of the column. After the injection the spine was X rayed immediately, six hours later, and again at the end of 24 hours. The Wassermann reaction in blood and cerebro-spinal fluid of all cases was negative. The cerebro-spinal fluid, as obtained by lumbar puncture, in all cases was colourless under normal or lowered tension, not spontaneously coagulable, and showed no increase of cells and only the slightest increase of protein. The Queckenstedt (jugular compression) test produced in the cervical case a rise in cerebro-spinal fluid tension of from 40 to 70 mm. only, thus indicating some obstruction in the cerebro-spinal canal, but in the thoracic cases the fluid tension quickly rose from 115 mm. to over 300 mm. in Case 1, and from 65 mm.

DONCASTER ISOLATION HOSPITAL.—The Doncaster Corporation's new Isolation Hospital, on the edge of the borough, which has cost £53,000, was opened recently. There are five blocks of wards and a sanatorium with accommodation for 98 patients, an administrative block, and a home for the resident medical officer.

to over 300 mm. in Case 2, and so failed to indicate any gross blockage of the canal.

Pathology of the Tumours.

The tumour was extramedullary in each case. In Case 1 it was soft, lobulated, and encapsuled, lying within and adherent to the dura posteriorly, and indenting but not infiltrating the posterior aspect of the cord. It was ovoid and nearly an inch in length, quite free from nerve roots, and was easily and completely removed with a piece of the attached dura. Case 2 also presented a soft lobulated tumour underneath and incorporated with the arachnoid but not adherent to the dura. Fully one and a half inches in length, it lay on the right anterolateral aspect of the cord, filling up half the dural canal and compressing and displacing the cord to the left. The fourth dorsal posterior root on the right side crossed the lower part of the tumour and had to be cut in order to facilitate removal, which was complete but piecemeal.

In Case 3 a hard lobulated mass was present within but slightly adherent to the right posterolateral aspect of the dura, and indented but did not infiltrate the right side of the cord. The mass within the dura measured about three-quarters of an inch vertically and was connected to a pedicle which passed through the intervertebral foramen between the axis and the third cervical vertebra. The inner end of this pedicle formed a congested bulbous swelling in the extradural space and the outer end was connected to a larger mass in the right side of the neck. The pedicle fitted the intervertebral foramen tightly and had produced an expansion of the opening by pressure. The mass in the neck was multilobular. A few small lobules lay close to the foramen and one, much larger, about the size of a pigeon's egg—the main portion of the tumour—lay between the muscular planes formed by the rectus capitis anticus major in front and the scalenus medius and levator anguli scapulae behind. All parts of the tumour appeared to be enclosed in a common capsule and no trace of the right third cervical nerve could be made out. The whole of the intrathecal portion of the tumour with the attached dura was removed piecemeal and the pedicle cut across flush with the dura. No attempt was made to remove the pedicle or the larger extraspinal portion of the tumour at this stage.

The tumour in Case 1 proved on microscopical examination to be a typical meningeal endothelioma. It was composed of small whorls of spindle-shaped cells with a considerable number of hyaline concentric masses, a number of them showing deposits of lime salts—so-called psammoma bodies—but only a few hyaline strands were visible. In Case 2 the tumour was also a typical meningeal endothelioma of similar type. The spindle-shaped cells were rather loosely arranged in small whorls and contained many hyaline strands and numerous hyaline concentric masses—so-called psammoma bodies—but no calcareous deposits.

In Case 3 the tumour was of a rather different type. Microscopically it was found to be a very cellular fibroblastic growth with rather a whorled formation. The spindle-shaped cells showed a marked tendency to palisade arrangement, especially around the vascular spaces. There were no hyaline concentric masses. The tumour appeared to be a neurofibroma and probably originated from the sheath of the third cervical nerve.

Clinical Features.

The principal clinical features of the three cases are briefly summarised below. The signs were those present when the patients came under our observation.

CASE 1.—A female, aged 42, had had symptoms for one year. Feelings of coldness and numbness commenced in the lower part of the right thigh and extended within six months to the corresponding part of the left thigh. A feeling of band-like constriction in these parts was next observed and shortly afterwards the right leg began to "drag," and the patient occasionally tripped over a stone and fell. Cold and numb feelings were next experienced in the feet, and these gradually spread up throughout both

legs and thighs. Two months later (eight months after the initial symptoms) the left leg began to "drag" also, so that the gait became spastic and jerky. At this time the patient began to experience involuntary flexor spasms of the hamstring muscles, first in the right leg but soon in both. Spasticity in the legs and the associated difficulty in walking became so marked that she was obliged to take to bed a month later (i.e., nine months after the onset of the initial symptoms). The lower part of the back and perineum next began to feel numb and, within a month of taking to bed, she began to experience at intervals a tight band-like feeling in the right side of the lower abdomen. This soon disappeared, but the corresponding part of the left side then became similarly affected. A feeling of tightness across the upper abdomen also appeared at this time, and the patient frequently experienced a sharp pain shooting from the angle of the left scapula round below the left breast. She then began to have considerable aching pain in the legs, the flexor spasms increased in frequency, and two months later—about 12 months after the initial symptoms—she came under our care. Normal desire to micturate was gradually lost during the illness, but she was able to empty the bladder voluntarily until after coming under our care. The bowels had been constipated since onset.

She showed complete and marked spastic paraplegia. Both legs were flexed at the knees and hips, and were painful. She was quite unable to stand or to move her legs, but there was no obvious muscular atrophy. Some cardiac failure was present; she was dyspnoic, requiring a bed-rest, and her feet and ankles were oedematous, and moist râles were heard at the bases of the lungs. Cystitis soon developed and later incontinence of urine and faeces. Sensory changes were present in both lower limbs and in the body up to a line encircling the trunk at the level of ensiform cartilage in front and the sixth dorsal spine behind. Sensibility to brush and pin-prick were diminished in front from the level of the ensiform cartilage down to the level of the umbilicus on the right side and to the level of the anterior superior iliac spine on the left; below these latter levels sensibility to brush and pin-prick was completely lost. Thermal sensibility diminished from the level of the ensiform cartilage down to the level of the anterior superior iliac spines, and was absent below this level. Dorsal sensibility was present but diminished from Poupart's ligament downwards—more so in the left leg. Posteriorly, sensibility to brush and to heat and cold diminished from the level of the sixth to the ninth dorsal spines on the left side, and from the sixth dorsal spine to the seventh space on the right side, and was absent below these levels. Sensibility to pin-prick was diminished on both sides of the back from the level of the sixth to the tenth dorsal spines and was absent below this. Vibration sense was absent throughout both legs, and diminished over the symphysis pubis and anterior superior iliac spines—more so on the left—sacrum, lumbar, and dorsal spines up to and including the tenth dorsal. The knee- and ankle-jerks were exaggerated on both sides, and ankle-clonus was present. Both plantar reflexes were extensor. The abdominal and epigastric reflexes were absent, but the arm-jerks were normal. The spinal level diagnosed was the seventh thoracic segment. Lipiodol was held up completely at the level of the disc between the second and third thoracic vertebrae. Six hours later, however, most of the lipiodol had passed right down to the lower end of the meninges, about one-sixth remaining at the above site, and a few drops being visible here and there on the way down. No further change was noticed after 24 hours. Partial "spinal block" was thus indicated.

CASE 2.—A male, aged 32, had had symptoms for ten months. He complained of a "cold feeling" in the front of the thighs and lower part of the abdomen, and on tugging in the thighs and lower part of the abdomen, and on tugging in both feet and legs. About three months later numbness of both feet and legs in addition. Gradually the right leg began to feel stiff and at this time a feeling of tightness across the lower abdomen, about the level of the iliac crests, was experienced for about two weeks. The bowels were persistently constipated, and after micturition he always felt as if the bladder were not completely emptied. Little change occurred until four months later when, with slowly increasing stiffness in the right leg, the right foot began to "drag," and both feet became so numb that he was "unable to feel the ground." One day, about a week after this, his right leg "gave way" under him, and shortly afterwards his left leg began to feel stiff also. Spasticity in both legs then quickly increased, so that he was unable to get about and began to experience spontaneous flexor spasms in one or both legs. The feeling of tightness across the abdomen then returned, he began to have much difficulty in controlling the urinary sphincters, and shortly afterwards he came under our care—ten months from the onset of the initial symptoms.

Both legs were moderately spastic and spasticity increased on flexion. Occasional twitching movements were seen in the

leg muscles. Incontinence of urine was present. (Cystitis developed shortly afterwards.) He was a sparsely-built man, thin, but without local muscular atrophy. From the level of the nipples to a horizontal line midway between the ensiform cartilage and the umbilicus sensibility to pin-prick was diminished. From one inch below the nipples down to the same horizontal line sensibility to a brush and to heat and cold was diminished. Below this level thermal sensibility was absent, and sensibility to brush and to pin-prick was absent on the right half of the body and in the right leg and almost absent on the left. Posteriorly pin-prick, brush, and thermal sensibility were diminished from the level of the seventh dorsal spine downwards. Pin-prick sensibility was reduced down to the level of the tenth dorsal space on the right side and the eighth on the left; brush down to the eighth on both sides and thermal down to the tenth. All three sensations were completely lost below these levels. Vibration sense diminished from the eleventh dorsal spine downwards, and was absent throughout both legs and over both anterior superior iliac spines. The knee- and ankle-jerks were exaggerated on both sides, the right more than the left; ankle-clonus was present and more marked on the right side. The plantar responses were flexor and equal. The abdominal reflexes were absent and the arm-jerks normal. The spinal level diagnosed was the fifth thoracic segment. Most of the lipiodol was held up at the lower part of the body of the second thoracic vertebra; the rest passed to the lower limit of the meninges leaving one or two droplets on the way down. There was practically no change in 24 hours. Incomplete "spinal block" was indicated.

CASE 3.—A female, aged 23, had had symptoms for ten months. After an attack of influenza a rounded swelling had appeared fairly suddenly in the right side of neck about six months before the onset of spinal symptoms. Quickly increasing to the size of a walnut, it had then seemed to remain stationary, except that occasionally it would be slightly painful and feel a little larger. Spinal symptoms began with numbness, loss of feeling, and weakness in the right hand. This numbness and weakness gradually spread up the right arm until, four months later, the weakness had become so marked that the patient was unable to feed herself with this limb. About this time also tingling sensations appeared in the right hand and trunk; and shortly afterwards she began to experience loss of feeling in the left hand. The left arm soon began to feel numb also, and weakness and tingling sensations set in. Two months later the right leg began to feel weak and "loose about the knee"—as if it would not support her—the right foot began to "drag," and tingling sensations were experienced in the thigh. In another two months the left leg began to feel stiff, the left foot began to "drag," and tingling sensations were felt in this thigh also, and the patient was only able to get about with the greatest difficulty and with assistance. At this time she accidentally burnt her left hand without feeling it. A month afterwards tingling sensations were experienced throughout both legs, and a tight band-like feeling around the chest at the level of the axillae. This feeling of constriction persisted, with occasional intermissions. About this time, however, sensation began to return in the right hand. About a month later flexor spasms began to affect the left arm and shortly afterwards she came under our care. The bowels were constipated and urinary symptoms were absent until after coming under our observation.

There was a rounded swelling about the size of a walnut on the right side of the neck, partly under and partly behind the sternomastoid, and with its upper edge about one and a half inches below the lobe of the ear. It was firm, non-fluctuating, and not adherent to skin or sternomastoid, but appeared to be fixed deeply in the neck. It was slightly tender at its lower part but only on deep pressure. Weakness and stiffness were present throughout both upper limbs, slight on the left and more marked on the right. There was also some weakness of the right shoulder muscles and a tendency to contracture of the flexors of the right forearm, hand, and fingers. The right arm was generally slightly thinner than the left but there was no local muscular atrophy. The lower limbs were spastic and uniformly thin below the knees. Lying in bed the patient could flex her knees and thighs but could only move her ankles and toes very slightly. She was quite unable to stand unsupported, but could take a few short steps if assisted and her body supported. Sensibility to brush, pin-prick, and heat and cold was diminished throughout the left lower limb and the left half of the trunk up to the level of the second rib in front and the spine of the scapula and second dorsal spine behind. Throughout the left upper limb sensibility to brush and pin-prick was diminished up to the level of the acromion process and down to the lower margin of the deltoid muscle in the axilla. Thermal sensibility was lost completely in the hand and a home for back of the left forearm and very much throughout the rest of this arm. Vibration sense

was diminished throughout the left leg, left anterior superior iliac spine, left forearm, right wrist, and over the vertebral spines from the second dorsal downwards. (With the exception of vibration in the right wrist the sensory changes in this case were unilateral.) The knee-jerks were much exaggerated and patella clonus was present—a little more easily obtained on the right side. The ankle-jerks were much exaggerated and clonus was present, slightly more marked on the right than on the left. Both plantar responses were extensor. There was a slight Oppenheim's reflex on the right side. Epigastric and abdominal reflexes were absent. Arm-jerks were all exaggerated, rather more so on the right side. The spinal level diagnosed was the fifth cervical segment. A small portion of the lipiodol injection passed right down to the lower limit of the meninges, the bulk, however, remained in the cisterna magna with a portion extending down to the middle of the body of the axis. Twenty-four hours later there was practically no change, so that an almost complete "spinal block"—the upper limit of which was at the middle of the body of the axis—was indicated.

Commentary.

These cases were operated upon under intrapharyngeal nitrous oxide oxygen anaesthesia. The operative technique and the after-treatment were essentially the same as described in our previous communication, except that in Cases 1 and 3 the dura mater was left open after removal of the tumour. In the case of the dumb-bell tumour (Case 3) only the intrathecal part was removed, it being intended to remove the extraspinal portion at a subsequent operation, but the patient continued to vomit after the operation and died rather suddenly 15 hours later. The autopsy revealed the cause of death to be acute dilatation of the stomach, the stomach almost filling the abdomen. The prognosis in the other two cases was considered rather unfavourable on account of the previous cardiac failure and the cystitis in Case 1 and the severe cystitis in Case 2. Both, however, stood the operation well and slowly and steadily improved afterwards.

In Case 1 the patient began to have some return of feeling in the right foot within a week of the operation, and ten days later she was able to feel both her feet and legs being touched with the hands. Three weeks after the operation the tight band-like feeling around the waist had disappeared and she was able to flex the right ankle and knee and flex and extend the toes. Both legs, however, were rather painful and somewhat more spastic than before the operation. Three and a half months after the operation she had regained complete control of the sphincters and she began her first attempts at walking again. By this time the stiffness in the legs had considerably lessened, but occasional flexor spasms occurred. When last seen, eight months after the operation, this patient was able to flex and extend the legs fully, although with some effort, for there was still some spasticity and adductor spasm. She was able, with some assistance, to take short walks daily, but when walking she kept her knees rather flexed and took short steps. Sensation had completely returned except for some diminution of vibration sense in the left ankle, diminished thermal sensibility in the sole of the left foot, and absent joint sense in the left great toe. Flexor spasms of the legs were still troubling her, particularly at night, and a slight feeling of constriction was present around the waist. The left plantar reflex was doubtfully extensor.*

In Case 2 sensation commenced to return in the legs two days after the operation. Within ten days he was able to draw the right leg up and could feel a pin-prick in this leg distinctly. A week later he could feel a pin-prick in the left leg and deep pressure in both, and two days later he began to regain control over the bladder. About ten weeks after the operation he could move both his legs, but spasticity had increased. A month later the spasticity had become very marked and adductor spasms so troublesome—his legs remaining crossed—that orthopaedic treatment was decided upon. The right obturator nerve was cut, tenotomy of the right adductor longus was

* Two months later her condition generally had greatly improved and she could walk much more freely without assistance.

performed, and the remaining adductors and hamstrings on both sides were stretched. These measures effectively corrected the "crossed-leg" deformity, but some contraction of the hamstrings persisted. Within a fortnight, however, he was able to lift both legs off the bed and move them at all joints. He had now, also, complete control over the bladder. Progress in walking continued slowly but was considerably hampered by increasing contracture of the hamstring muscles, preventing him from straightening his legs. Consequently, some eight months later, further orthopaedic treatment was undertaken. Tenotomy of the hamstrings on both sides was performed and the legs were put up in plaster, fully extended, for three weeks. At the end of this period he commenced walking again, was able to stand erect, and soon was getting about with much less fatigue and more comfort. The bowels and bladder were acting normally. When last seen—some 15 months after the removal of the tumour—he looked and felt very well indeed. He was able to walk erect and quite smartly but with just a suggestion of stiffness at the knees. He had no tingling, pains, or spontaneous flexor spasms in his legs and no tightness around the body. He had complete control over his sphincters but constipation was rather troublesome. While the legs showed spasticity in extension, he could flex and extend them easily at all joints. The knee-jerks were exaggerated and equal, and ankle-clonus was present on both sides. The plantar responses were slightly extensor. Sensory recovery was marked. Sensibility to pinprick had completely recovered. Thermal sensibility also was normal, except for a zone of slight diminution encircling the body from the level of the nipples to that of the ensiform cartilage. Sensibility to the brush was still diminished, but only slightly so, in the legs and trunk up to about the seventh dorsal spine behind and the nipples in front. Vibration sense was still slightly diminished from the knees downwards, a little more so in the right leg than in the left.

Clinical and Laboratory Notes.

A NOTE ON THE PRESENCE OF ANTIBODIES TO HERPES VIRUS IN POST-ENCEPHALITIC AND OTHER HUMAN SERA.

By C. H. ANDREWES, M.D., M.R.C.P. LOND.,

MEMBER OF SCIENTIFIC STAFF, NATIONAL INSTITUTE FOR MEDICAL
RESEARCH;

AND

E. ARNOLD CARMICHAEL, M.B., M.R.C.P. LOND.,

CHIEF ASSISTANT, PROFESSIONAL MEDICAL UNIT,
ST. BARTHOLOMEW'S HOSPITAL.

Two main theories concerning the aetiology of encephalitis lethargica are current. Some hold that the disease is caused by the virus of herpes simplex, which under exceptional circumstances becomes neurotropic in man. This view is based on the occasional recovery of herpes virus from the brains of patients dead of encephalitis lethargica and on the fact that herpes virus can produce not only an acute or chronic encephalitis in rabbits, but also, as Zinsser¹ has shown, a chronic encephalitis in certain monkeys which is not unlike encephalitis lethargica in man. Others, however, are unconvinced by this evidence and maintain that the cause of encephalitis lethargica is an unknown specific neurotropic virus. (See Zinsser's² recent review of the problem.)

It seemed that some light might be thrown on the aetiology of encephalitis lethargica by examining sera

from post-encephalitic patients for antibodies to herpes. If herpes virus were the causal agent of encephalitis lethargica, antibodies might be expected to be present in view of the following considerations. First, many neurologists believe that post-encephalitic parkinsonism is a manifestation of a chronic infection with the agent of encephalitis and not a mere residuum due to destruction of nervous tissue. Secondly, rabbits infected with herpes, including those suffering from a chronic form of encephalitis, possess neutralising antibodies in their serum. Flexner³ reported in 1923 that convalescent epidemic encephalitis serum was somewhat more protective against herpes virus in rabbits than were a few samples of normal human serum. Since our investigation was begun Zinsser and Tang⁴ have published the results of a study on the same lines. They found that 39 of 45 post-encephalitics (86.7 per cent.) had antibodies to herpes in their serum, while only 11 out of 17 adult controls (64.7 per cent.) showed antibodies. Normal children gave an even lower percentage of positive results (43.4 per cent.). Zinsser and Tang were naturally reluctant to draw conclusions from these figures. They tested for anti-herpes properties in sera by incubating the serum to be tested with 2 to 4 minimal lethal doses of virus and inoculating rabbits intracerebrally. This method, though it apparently gave consistent results, is expensive in animals and allows very little margin for possible variation in the susceptibility of the rabbits.

Our investigations were undertaken because we had at hand a simple method of testing for antibodies to herpes. We found, as Gay and Holden⁵ and Wilson Smith⁶ have done, that some strains of herpes give very satisfactory lesions when inoculated intradermally into rabbits, and that with such a technique sharp neutralisation of virus by immune serum can be shown. We used a strain (E.L.I.) kindly given to us by Dr. J. R. Perdrau; this at first gave unsatisfactory intradermal lesions, but after a few passages in tissue cultures was very satisfactory for our purposes. The virus multiplied readily in cultures of rabbit testis in dilute rabbit serum, as lately described by one of us (Andrewes⁷). Fluid from tissue culture was mixed with an equal volume of immune serum, and after a few minutes' contact at room temperature, 0.1 c.cm., was inoculated intradermally.

Results.

Human sera were found to fall sharply into two groups. Either they did not influence at all the size of the lesion produced by the virus, or they neutralised a thousand infective doses completely. It will be seen from Table I. that 21 out of 28 (or 75 per cent.) control sera contained antibodies to herpes; such antibodies were less evident in the few sera examined from normal persons, chiefly medical students, than in sera of assorted hospital patients, but the possible significance of this difference has not been further studied. In Table II. are set forth the results of testing the sera of 25 post-encephalitic patients; brief details are given of the history of their disease. Antibodies were found in the serum of 18 out of 25 patients (or 72 per cent.), approximately the same percentage as in the control group.

All the patients whose serum was tested were asked whether or not they had ever suffered from "herpes simplex," the nature of which was described to them. Very few replied in the affirmative, but it is not felt that much reliance can be placed upon the answers obtained. In addition to the unselected group of normals in Table II., sera were examined from seven subjects, all workers at the National Institute for Medical Research and all liable to frequently recurring attacks of labial herpes. Antibodies were present in all seven of these sera. It is of particular interest that one of them had had an attack of herpes six days before he was bled, while another had an attack four days after blood was taken. Herpes simplex is one of the few known virus

within the last four years. I do not think the method so suitable to children under 14 years of age, since to them a general anaesthetic is usually less alarming than the appearance of electrical apparatus. The process here called diathermy is strictly a combination of true diathermy and fulguration. Broadly speaking, the stage of true diathermy coincides with the production of sufficient heat within the tonsil to kill the tissue and boil contained liquids. Fulguration is the condition of electrically "arcing" off the surface of the tonsil in order to seal efficiently and permanently both arteries and lymphatics. There are no contra-indications to this method which would not apply to the simplest of surgical operations. The general health of the patient should be noted and oral sepsis eliminated as far as possible. As already mentioned, each tonsil is surrounded by a maximum surface of mucous membrane, and this fact ensures the success of cocaine spray anaesthesia. No general anaesthetic has ever been required and, of course, the use of ether would be precluded by the presence of high tension electricity. I have found it quite unnecessary to inject cocaine, and it has always been sufficient to spray the throat with not more than 2 grains of cocaine hydrochloride freshly dissolved in two drachms of water.

The tonsillar electrode is usually a small metal ball mounted on a curved insulated handle of ebonite. A variety of holders have been constructed to cope with any angle of application. As the result of experiment, no advantage was found in using more than one indifferent electrode, and finally a sheet of thin lead, 8 in. by 6 in., has been selected as standard; it is covered by four thicknesses of plain lint saturated in 20 per cent. salt solution. This electrode is securely strapped to one wrist and bears a large M.S.A. diathermy terminal. The frequency of oscillation of the diathermy machine is not at all critical, and the several well-known makes of apparatus which I have tested all gave excellent results with a diathermy current of two amperes. This current can constantly be obtained once the necessary setting for the particular machine has been determined and, when used with the resistance of an average patient, rapidly causes a rise of temperature in the tonsil to approximately 100° C. As soon as anaesthesia is complete the indifferent electrode is fixed to the forearm, the patient comfortably seated in a supporting chair, and the tongue depressed by means of a glass spatula. The active electrode is then placed in firm contact with the tonsil and the current switched on. The tonsil soon shows, radiating from the centre of the active ball electrode, a zone of coagulated tissue, which rapidly desiccates. Complete destruction of the tonsil is effected slightly beyond this area of coagulation. The whole process lasts but a few seconds, after which the active electrode is deliberately arced a few times from the surface of the tonsil in order to seal any vessels. It may be a little difficult at first to determine the depth to which coagulation has taken place, especially if the operator is unfamiliar with more general surgical diathermy. Much useful information was acquired by the writer from sections of raw beef treated with varying electrodes and intensities. It is occasionally advisable to complete the tonsillectomy in two, or very rarely, three, stages, but this only applies to very large tonsils, or, alternatively, to extremely nervous patients.

Post-operative Procedure.

The patient is invariably seen at the end of a month, and again after three months. Should a fragment of lymphoid tissue have escaped, it is, of course, removed at this stage. There is no need to hospitalise the patient and the discomfort is relatively slight. The operation is practically painless. During the 36 hours or so following the treatment the peritonsillar tissue becomes cedematous, which I believe to be the rule in all operations involving mucous membrane. A suitable hypnotic such as Allonal will ensure the first night's sleep. I find approximately 20 per cent. of cases show a rise in temperature, which rapidly subsides in a few hours, and for this reason I have lately ordered all patients to remain in bed for 48 hours after operation. An antiseptic mouth-wash is ordered to be used after each meal, but gargling is absolutely forbidden, lest undue strain be placed on the throat. The coagulation slough commences to separate in a few

days and the process continues for about ten days or a fortnight. During the latter part of this period the slough may prove slightly malodorous, but this does not seem to be realised by the patient, and of course disappears with the departure of the slough. Secondary infection of the slough or underlying tissue has not occurred in any instance. The general reaction always remains slight and the local disturbance reasonable. No secondary hæmorrhage has occurred throughout this work. A soft glassy scar, with practically no contraction of tissue, invariably results, and is assumed to be evidence of a downgrowth of epithelium.

I believe that this application of diathermy to tonsillectomy possesses at least all the advantages of other methods, and yet none of their disadvantages.

Medical Societies.

HARVEIAN SOCIETY.

At a meeting of this Society on April 10th, with Dr. P. MONTAGUE SMITH, the President, in the chair, Sir THOMAS HORDER opened a discussion on

HIGH BLOOD PRESSURE.

His interest in the subject, he said, was chiefly clinical; he differentiated between three types of case. In the first group he placed those patients with evidence of definite organic disease due to arteriosclerosis or atheroma—i.e., those in whom there was diffuse arterial degeneration. This was the largest group of the three. Patients with this type of high blood pressure showed associated changes in the heart and kidneys, and later developed the renal condition severally termed granular kidney, interstitial nephritis, and gouty nephritis. Symptoms were protean and included heart failure, angina, renal insufficiency, retinal changes, hæmorrhages, thrombosis, and uræmia. Prognosis and treatment were less hopeful with this type of case than with the others, and it was important to assess the state of the myocardium. The second group was also the next largest. It comprised those cases in which the onset of symptoms and the development of high blood pressure were associated in the mind of the doctor, but in which there was no certain evidence of organic change in the heart, kidneys, or blood-vessels. These cases he classed as hyperpætics, but the line dividing them from the arteriosclerotic type was indefinite. Finally, there was a small group in which the renal element was dominant; there might be a mixed nephritis or frank parenchymatous nephritis. The patients were usually women in the late thirties with a blood pressure registering 240 to 300 systolic and 120 to 150 diastolic. They had albuminuria, retinal changes, and no œdema; they usually died in uræmia.

Hyperpæsia.

The cases in the second group might be subdivided into five minor classes. First, the plethoric type of man of sedentary habits, with a tendency to overeat. Hypertension in these cases might be in some degree compensatory to cope with increased metabolism. Secondly, there were cases where hypertension was due to some exogenous poison, the commonest of which was alcohol. Thirdly, there were menopausal cases. Women in the late forties often entered on a stage of hypertension which might last some months or years and then, gradually or occasionally suddenly, subside. At one time he had thought a systolic pressure of 175 the limit beyond which these cases should be considered pathological, but he had seen women with a systolic pressure of over 200 emerge from this phase, and he was no longer prepared to set a definite limit. The diastolic pressure did not rise *pari passu* with the systolic in this group, and the

greater the lag the better the prognosis, since the diastolic pressure represented the permanent strain on the heart and vessels. Men often seemed to go through a similar phase of hypertension, but later in life than women. Boys at puberty often experienced a similar rise in pressure, especially those boys in whom the heart had given cause for concern. Some cardiologists said that they could detect thickening of the brachial arteries in these cases but he did not know how they did it. He considered that the rise in tension might be a compensation for heart strain, since he was not one of those who held that the heart could not be strained by exercise. Fourthly, there was a group of nervous hyperpiesics. In many of these the patient's knowledge of his high blood pressure helped to keep it high. Good effects could be got in these cases by encouraging equanimity. Finally, were there possibly cases which might be called essential hyperpiesia? Such patients had a blood pressure of 200 systolic, 100 diastolic, all their lives, without evidence of toxic or other causes. They complained of headache, giddiness, and lassitude. If these cases were understood they might help to explain raised arterial tension in general. Were they, perhaps, the expression of an endocrine disturbance, and, if so, of the adrenal or the pituitary, or both?

The will-o'-the-wisp of focal sepsis had received much attention in cases of hyperpiesia. A diffuse sepsis might also be considered, affecting the whole of the upper respiratory passages or a large section of gut. The evidence was elusive. Our predecessors who called these patients gouty were as near the truth perhaps as ourselves in our eternal search for sepsis.

Exacerbations of symptoms occurred from time to time, accompanied by waves of hypertension. Intensive treatment should be undertaken during these attacks. The prognosis was serious until organic disease was excluded; even then a patient with high tension could not be regarded as a good life. He disliked any case in which physical examination failed to reveal anything abnormal, and if there was a family history of arterial disease he liked it even less. A man was not only as old as his arteries, but his arteries were the resultant of the arteries of his forbears.

Treatment.

Early diagnosis of high tension should lead to prophylactic treatment. It was impossible to change a temperament, but strains and stresses could be diminished. Reassurance in these cases was a form of treatment, and, if accepted, often caused a fall in tension. It should be explained that high blood pressure was not a disease but a symptom, and probably a valuable adjustment. Rest and diet must have their place; it was less important to limit the diet in any particular than to reduce the whole amount taken. Much fluid should be avoided, since water was secreted by the kidneys, not merely diffused, and therefore threw more work on them. Portal depletives such as mercury and salines were valuable, and constipation should be corrected. Warm baths and high frequency had their place, and venepuncture was valuable during exacerbations; he preferred to remove 50 to 100 c.cm. of blood daily for a few successive days rather than to take a larger quantity on a single occasion. Drug treatment included iodine, iodides, and occasionally nitrites. Digitalis was often helpful; in these cases the heart often needed tonics when it was erroneously imagined that depressants were required. Anabolins were still on trial but had given no impressive results so far. Thyroid and bromide were useful for menopausal and nervous cases. For each individual the state of the heart, the kidneys, the vessels, the nervous system, and the tissues must be assessed. Success depended on the care given to the individual case.

Discussion.

Dr. GEOFFREY EVANS agreed with Sir Thomas Horder that it must be decided in every case whether the condition was functional or organic, but he

doubted whether a distinct line could be drawn between the two. In the menopausal cases he had found that the blood pressure rose, and then either returned gradually to normal, or remained high and increased, or else fell below normal and remained there. The first of these courses he regarded as indicative of functional disease, the second of organic. The aetiology was the same; possibly some pathogenic agent caused a simultaneous change in function and in structure, but one change might outbalance the other. The prognosis was better when structural changes were not apparent. The cause of the condition should always be sought. He described the case of a medical student who at the age of 19 was told by one doctor that he had a high blood pressure, and by four that he had not; he lived a tranquil temperate life to avoid arterio-sclerosis, and at the age of 48 had a systolic pressure of 240 and a diastolic of 120. He had been developing this hypertension gradually, without any cause being discovered. Progress of the disease was in waves—stationary phases followed by exacerbations. Sir Clifford Allbutt had given the name of hyperpiesia to those cases with persistent high tension and without uræmia in whom death usually occurred from cerebral hemorrhage. These were the cases which did not respond to rest and diet. At about 35 they began to develop retinal hemorrhages; a few years later renal symptoms appeared, and at 45 they gave the typical picture of chronic interstitial nephritis. They died of uræmia, cardiac failure, or hemorrhage. As structural and renal changes developed the prognosis became worse, but even in the absence of such changes death might occur from cerebral hemorrhage.

Dr. J. F. HALLS DALRY said that hypertension was a symptom of many causes; it was therefore difficult to formulate a scientific treatment. Over-feeding led to the retention of waste products which were not easily secreted by the kidney. According to the French school the liver was an important detoxicating agent; he considered that in this condition the liver dysfunction was part of the general condition. Exercise was more important to restore its action than chologogues or salines. Control of the condition should be aimed at rather than treatment. The patient should regulate his life and his diet; meat appeared to have no effect on the damaged kidney, and provided the diet was adapted to the minimum metabolic level it need not be otherwise altered. As to intestinal toxæmia, the only toxin which had so far been investigated had a depressant, not a pressor, action; oral sepsis was more important. He did not agree that a man was as old as his arteries; many patients with seriously diseased arteries lived for years. The renal condition had much more effect on the prognosis. Attempts at reduction of pressure by drugs were usually dangerous; in most cases the high pressure was essential for kidney action. The diastolic pressure was essential for kidney action, because it was more constant and less affected by emotion. A diastolic pressure of more than 120 was usually indicative of disease of the kidneys. Apoplexy usually occurred in those cases with the highest pressures, but in those between 100 and 100 systolic. He only used venesection as an emergency measure, and started the patient for three days afterwards. He had had no good results with anabolins, and the results to be obtained from potassium iodide would be obtained equally well with French form of iodide. The iodine, not the potassium, was important.

Dr. A. H. DOWTHWAITE said reassurance was of little value unless it was given during an exacerbation, and the patient must be reassured by reduction of pressure while attack is in progress. He found iodides, nitrites, and anabolins of little value. Thyroid extract had been used in menopausal cases, but as he had been venesection every three months he had not found it of much use. He had found that Guy's muscular injections of ethylcholine 0.1 g. were being given in a course.

effected a reduction of pressure with relief of symptoms lasting for a period up to six weeks. He thought that intestinal toxæmia was associated with high blood pressure in those cases with fœtor oris and sallow complexions, since these symptoms always increased during exacerbations. Experiments on intestinal toxins had been carried out by injection of a dose of the toxin into an animal; the fact that no rise in blood pressure resulted gave no indication of what would result from chronic intoxication. These substances might act by causing an hypertrophy of the suprarenal medulla, with increase of circulating adrenalin. A similar mechanism was at work during the menopause, when the ovarian hormone failed to exert its counteraction on the suprarenals, and accounted for menopausal hypertension.

Dr. ADOLPHE ABRAHAMS said that the school of Lewis did not hold that the healthy heart could be strained by exercise, but the toxic heart might. Might not some of the boys at puberty seen by Sir Thomas Horder be cases of veiled renal disease? The subject would be less involved if the height of the blood pressure was always correlated with the symptoms. He took it that Sir Thomas Horder agreed that practitioners must insist that hypertension should not be considered to be arterio-sclerosis in every case.

Dr. GILBERT ORME said he had seen many cases of transient hypertension during the late forties among male mill hands in the North of England. In all the cases which survived normal tension was regained after about two years.

Dr. R. COVE-SMITH said that probably everybody had his own normal standard of blood pressure, and no definite line should be drawn in deciding where abnormal pressures began. He found it difficult to bring increased tension into line with cardiac strain as a compensatory mechanism. Digitalis was a useful stimulant to the myocardium in cases of hypertension, and he knew of no evidence that it increased the blood pressure in the normal man.

Reply.

Sir THOMAS HORDER said that he could not prove that his young boys were not cases of potential nephritis, but he had never heard of any nephritic developments later. Changes in the vessels were not necessarily an indication of their condition; they might be healed, in which case the man was as young as the repair of his arteries. He treated his patients during exacerbations, not with reassurance merely, but with rest in bed, a vegetable, fruit, and milk diet, a fast day once a week, intensive iodine, and venesection. As to heart strain, if Dr. Abrahams would watch the finish of the boat-race he would see the text-book picture of heart strain among the rowers: pallor, dyspnoea, and the typical facies. If the coronary circulation was under the same control as the general circulation, then hypertension might very well be compensatory for heart strain by increasing the blood-supply to the myocardium.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.

At a meeting of this Society held on April 9th, Mr. C. FERRIER WALTERS, the President, being in the chair, Dr. A. D. FRASER read a paper on the

CAUSAL ORGANISM OF ACUTE RHEUMATIC FEVER

and its relationship to chronic rheumatism, cancer, and other diseases. An investigation into the pathogenesis of acute rheumatic fever had, he said, culminated in the isolation of a causal organism and the reproduction of the disease in animals. The organism had a very complicated life-history and had been found associated with many other diseases of obscure origin. It was seen in an Aschoff nodule as a nuclear body occurring singly or in pairs like dumb-

bells, giant pneumococci, or a cottage loaf. It might be surrounded by a clear halo, as if encapsuled. The staining reaction to hæmatoxylin varied, being sometimes dense black, sometimes light brown. It could not be identified by special stains. A Gram-positive coccus had been isolated from a case of rheumatism. It grew well now on weekly subculture and required no special media. It was non-hæmolytic and formed acid with glucose, lactose, maltose, saccharose, and salicin. It acidified and clotted milk and produced small, uniformly pink colonies on bile agar. On nasgar the colonies were moderately large, rather opaque and moist, with even edges. It looked the same after repeated subculture as it had at first. It gave the impression of reproducing by budding. Cultures had been injected intravenously into rabbits and had caused no obvious symptoms beyond wasting, but the animals had died in less than eight weeks. Autopsy revealed large firm vegetations on the mitral and aortic valves and small white areas in the kidneys. Microscopically there was marked interstitial fibrosis of the inner half of the myocardium and the papillary muscles. In the outer half there were small focal areas of cells amongst disintegrated muscle-fibres; these consisted of large irregular cells with densely staining nuclei together with the cottage-loaf cells. The vegetations on the valves consisted of masses of cocci, mostly Gram-positive. There was, however, no inflammatory reaction in the underlying tissues. The renal abscesses proved to be more in the nature of infarcts, but no cocci were found in them. Culture produced a pure growth of the same coccus as had been injected, and this culture produced the same lesions when injected into another rabbit. The lungs showed rheumatic pneumonia and two curious types of structure lying in the small arteries or capillaries. One type was an irregular mass of nuclear material without definite structure, with rounded, clearer, bulging ends. Their appearance suggested sporulating hyphæ of some kind of fungus. Some of them clearly showed the conjugation of two cells within a capsule, one smaller than the other. The other type was a mass of acidophil cytoplasm containing small particles of nuclear material of irregular shape and size. Around these structures was marked endothelial proliferation, while the alveoli contained many cells and sometimes fibrinous exudate, together with many cottage-loaf cells and cells with budding nuclei spores.

Dr. Fraser then described the post-mortem findings in a case of chronic rheumatic fever which died during an acute attack. The large bowel had shown acute hyperæmia with black ridges running along the mucosa in the long axis of the bowel and scattered ulcerated areas, covered by a yellowish-brown thin membrane. Examination of smears from the ulcers had shown the usual flora with a predominant large bacillus, varying in its reaction to Gram stain. Among masses of mononuclear cells in the bowel wall had been polymorphonuclear leucocytes and cells with the budding nucleus. There were also large diplococci, some of which took Gram stain. Two fungi had eventually been isolated from the ulcers.

The Oömycete and the Ascomycete.

One of these fungi, an oömycete, was parasitic on the other, an ascomycete. The latter had not yet been obtained in pure culture. *Ascomycetes rheumaticus*, as he called it, grew well on all ordinary media and was a facultative anaerobe. It formed acid in glucose but had no effect on other sugars. In milk it caused a slight acidity and opalescence. It did not liquefy gelatin. Its colonies on nasgar were large, smooth, and waxy with irregular edges, and after some time hyphæ grew down into the medium. For the first day or two the cultures were like budding yeast cells, but longer oval cells appeared later and long septate branching hyphæ with large rounded cells at their ends. Occasionally two cells could be seen united by a conjugation tube. Similar cells were found in the lungs of rabbits injected with this organism; the animals died within a week, with nodules in the heart, kidney, brain, and intestine.

Oömycelles rheumaticus reproduced itself by oöspores and zoöspores. It fermented glucose, lactose, mannite, salicin, and maltose, and acidified and clotted milk. It grew well on most media, but not on carrot, unlike the ascomycete, and was a facultative anaerobe. It was a slender, septate, filamentous organism, rapidly breaking up into coccoid bodies and motile bacilli in culture. In shake cultures of glucose nasagar the medium was blown apart as if with *Bacillus tetrahii*. Rabbits died in a few days when cultures were injected; their lungs showed many small mononuclear cells staining sky-blue with Leishman's stain. The organism was found in the blood and lung juice, and when cultured thence usually produced colonies of bacilli and cocci. The oömycelle thus had a sporulating hyphal stage. It also had a gametophytic stage which was seen in the meninges and cortex of infected animals. When the gametophytic nodules were cultured in broth, numerous motile short, fat, Gram-positive bacilli appeared. These lost their motility, became Gram-negative, and split into small Gram-negative diplococci. The bacillus formed acid and gas in glucose, lactose, mannite, maltose and salicin, and acidified milk but did not liquefy gelatin. On nasagar it formed large, smooth, glistening colonies with a more or less even edge. The small diplococcus produced small opaque yellowish colonies.

Subcutaneous injection was the best method of reproducing the disease, and the result depended on the stages injected. Typical rheumatic endocarditis and pericarditis had been produced. The lungs reproduced the appearances seen in human rheumatic fever and yielded the conjugating cells of the ascomycete. In successful cases the synovial tissues showed cells and structures identical with those formed by the oömycelle, and the meninges and bowel also had typical lesions.

The Fungi in Other Diseases.

The sporangial cells and cottage-loaf cells of the oömycelle were to be found, said Dr. Fraser, in the tooth sockets in chronic rheumatism, and bacillary filaments and gamete cells in a mucinous matrix might be seen in the cheesy masses in crevices or pockets of the teeth. The organisms had also been found in sinus washings and pus from acute otitis and mastoiditis, in two cases of nasal catarrh, and in almost every case of tonsillitis, and in a number of catheter specimens of urine from cases of infection of the urinary tract.

In polyps and other simple tumours, spores and sporangial cells were always present, while the amount of fibrous mycelium varied. Cancers showed the same features and in addition cyst-like cavities containing variously shaped nuclear bodies within a clear membranous capsule. Tumours with these cysts putrified very rapidly and yielded short, thick, square-ended bacilli having all the culture characteristics of the oöspore bacillus. Sarcomas had been found to contain a predominating number of the tubular mycelial hyphae. The urine and sputum of cases of neoplasm always contained some of the elements of the oömycelle. The fibrous mycelium and oöspores of the oömycelle had been found in a collection of gastric ulcers, gall-bladders, vaginal smears, and sputa from pneumonia, as well as in the stools of infantile diarrhoea.

Discussion.

The PRESIDENT congratulated Dr. Fraser on his work. He queried whether there might prove to be some relationship between this oömycelle and the streptococci which Rosenow had found so widely distributed. He asked if Dr. Fraser had any idea as to the source or original host of this fungus.

Dr. CAREY COOMBS said that Dr. Fraser's presentation of his views was such as almost to persuade one to believe in this all-pervading fungus. For the present, however, he felt obliged to adopt an attitude of reserve, for the following reasons: (1) He had examined specimens from a considerable number of

cases of acute rheumatic infection of the heart and other tissues and the appearances that he had seen were identical with those described by Dr. Fraser. The dumb-bell cells, however, he had regarded as phases in an endothelial reaction to irritation. (2) The experimental lesions that Dr. Fraser showed were similar to those which he (Dr. Coombs) had seen in animals inoculated with streptococci derived from a number of sources both in this country and elsewhere. (3) The indirect evidence in favour of a streptococcal basis of rheumatic infection was, he thought, worthy of note; there was, for example, its relation to tonsillitis, a lesion thought by most observers to be streptococcal in origin. If Dr. Fraser's view that streptococci are but one phase in the life-cycle of a fungus were true, the whole of bacteriology must be rewritten.

Dr. P. WATSON-WILLIAMS expressed surprise that Dr. Fraser should not have found sporangial cells in rheumatic pneumonia, but he recalled that Poynton and other observers had failed to find any organisms in Aschoff's nodules. He had frequently had washings from nasal sinuses examined by direct smears. As a rule nothing but morphological cocci had been reported present, but it was true that occasionally yeast-like bodies had been described in the smears.

Dr. FLEMING asked whether Dr. Fraser's theory helped to explain the peculiar uniformity of the incubation period which followed streptococcal infection.

Dr. ALEXANDER asked if Dr. Fraser thought that this oömycelle converted healthy tissue cells into cancer cells.

Dr. R. C. CLARKE found some difficulty in believing that such different diseases as colds in the head, gastric ulcer, erosions of the cervix, and glioma of the brain were merely varying reactions to the same infection.

Dr. A. T. TODD said that by the injection of simple serum in animals similar rheumatic and cardiac lesions had been obtained. He suggested that the effects in Dr. Fraser's animals might be due to anaphylaxis. He agreed with Dr. Fraser that there was an antagonism between chronic rheumatism and cancer; why this should be so if the two conditions were caused by the same organism he did not understand.

Reply.

Dr. FRASER admitted that the whole book of bacteriology would need to be rewritten if his observations proved correct: he recalled American observers who had recently shown mutation between bacilli, cocci, and amoeboid organisms. He claimed that the typical pericarditis which he had produced by the injection of the oömycelle in animals was not produced by an injection of streptococci. All sorts of unknown appearances had been explained by calling them phases in inflammatory reaction or contamination. A few months ago he had described true Aschoff's nodules in the lung. He pointed out that sporangial forms became unrecognisable in dry smears, but showed their definite structure in wet preparations. He was convinced that many cases of pneumonia were due to this mycotic infection; the pneumococci if carefully examined appeared to be in reality oömycelles. Cancer was a fungous growth of oömycelles and ascomycetes; the spermatozooids entered the tissue cells and activated them so that they became cancer cells. He thought he had only got on to the edge of a new group of infecting agents, but at any rate with this fungus he could produce experimental rheumatic lesions in animals. He had never seen anaphylaxis in an animal produce conjugating cells in the lungs.

BURNING A HOSPITAL.—Owing to the Dorset County scheme for a new institution, Yeovil Isolation Hospital, at Windwhistle Bridge, a few miles away, is no longer needed. Having in view the possibility of infection the Town Council decided to burn the building, and last week it was saturated with paraffin and petrol and completely destroyed.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

At a meeting of this Society held on April 11th the chair was taken by Dr. J. J. BUCHAN, the President, and a discussion on

MENTAL DEFICIENCY AND LUNACY IN RELATION TO PUBLIC HEALTH

was opened by Dr. W. M. ASH. The relation between mental deficiency, lunacy, and public health was, he said, of the closest, and any attempt at separation would be generally inadvisable. Up to the end of the nineteenth century mental deficiency and lunacy had been dealt with by nothing more nor less than a brutal prison service, but to-day they were on a par with other public health services, and prevention should start at an early age. The object of child guidance was to unravel the tangle of social, physiological, medical, and psychological conditions which caused a particular child to become a misfit in society. Here was an excellent example of team work. The social, physiological, and medical members of the team were already part of the public health service. The psychological member should also be a part of that service, and his clinic should be a department of the general maternal and child welfare and school clinic. The importance of the early recognition of mental defect was admitted by all, and school medical officers were supposed to be capable of deciding when expert advice was necessary. The expert should therefore be available as part of the school medical staff. The suggestion that mental health in school children should be under an independent mental health service was not a good one. Mental and physical health could not be separated, and a dual arrangement would cause overlapping and unnecessary interference and expense. Nor was there any line of separation between mental deficiency under and over the age of 16. Children under five, children of school age, adolescents, and adults formed a continuous series at any phase of which mental hygiene was and mental treatment might be necessary. The purely legal breaks at the ages of 5 and 16 were fortunately minimised by the happy circumstance that the Chief Medical Officer of the Ministry of Health was also the Chief Medical Officer of the Board of Education, while the Ministry of Health was the parent body of the Board of Control. Similarly, the local medical officer of health was also school medical officer, maternity and child welfare officer, and often mental deficiency officer, and received information from the time of the birth of the child under the Notification of Births Act. This unity of health service provided continuity of supervision throughout life. Again, there was no line of demarcation between the dull and backward and the feeble-minded or between the educable and the ineducable defective, and there was great advantage in having them all under one control. There was, in fact, no phase of a mental health service which could not with benefit be incorporated into the existing organisation of the public health service. The expert on mental diseases should be on exactly the same footing and as much an integral part of the public health service as the expert for tuberculosis, orthopaedics, or ear, nose and throat.

The health visitor was maternity and child welfare nurse, school nurse, tuberculosis nurse, mental deficiency visitor, blind persons' visitor, and now infant life protection visitor. She was essentially a highly trained woman, her duties carried her into almost every household within her area, and she was almost universally welcomed as an advisor and a director as to where expert advice could be obtained. Mental deficiency carried with it a stigma, and a special visitor from a department dealing with mental health would often be resented. Earl Russell had urged in the House of Lords that early mental treatment should at all costs be kept away from the

machinery of insanity. Obviously the best person to use as the first line of ascertainment in mental health was the general health visitor.

Unity of Command Essential for Efficiency.

The report of the Mental Deficiency Committee strongly urged close coöperation between the mental treatment service, the poor-law and lunacy administration, the public assistance committee, and the education authority. Coöperation was all very well in theory, but if the best practical results were to be obtained unity of command was essential. The Board of Control and the Royal Medico-Psychological Association were opposed to making medical officers of mental services part of the staff of the public health service, but their objections were not very convincing. The suggestion that such officers would not be of senior standing was without foundation. The heads of departments in Derbyshire were entirely independent clinically, and Dr. Ash was merely their administrative chief. It had been said that the administrative officer was not a mental expert, but nor was the mental expert an administrative expert. The administrative officer did not claim to be an expert in the various departments which he administered at present. The mental expert would soon find that detachment of his service would not make him independent but would bring him into subservience to a layman, probably a lawyer, as had happened under the Education Act of 1921 and the recent draft order under the Local Government Act, 1929, whereby school medical officers were placed under directors of education and poor-law medical officers were to have been made subservient to the public assistance officer. In conclusion, Dr. Ash deprecated the tendency to specialisation.

Dr. REGINALD WORTH outlined the provisions of the Local Government Act and the Mental Treatment Bill. He supposed that a general health committee for the treatment of physical and mental illness would be one of the most important branches of the public assistance committee in each county, and that mental health would require a special subcommittee to provide for the treatment of all mental disorder. Here at last was an opportunity for the treatment of the mentally sick and defective to rejoin the stream of general medicine. The centralisation of mental hygiene under one authority in a local government area was a sound policy, but its success would depend upon the administrative machinery adopted. The Royal Medico-Psychological Association had always urged that the mental hospital and mental deficiency services should not be dissociated.

The Mental Treatment Bill.

The passing of the Mental Treatment Bill was a great event; while preserving ample safeguards against wrongful interference with liberty it provided facilities that could not fail to result in widely extended early treatment which would ultimately prove preventive. The opportunity which Clause 5 afforded for early treatment was of the highest value, but the requirements introduced during the committee stage were seriously disappointing. The committee had left very little difference between "recommendation" and "certification," a most important distinction if "back-parlour" treatment was to be avoided. All that should be asked of the recommending practitioners was a declaration that the person was incapable of volition and likely to benefit by temporary treatment. Safety lay in notification and visitation, and not in any enlargement of the terms of recommendation. Altogether too much stress had been laid in the debates upon the inspection of institutions. Visitation involved much more than inspection. No doubt the effect of conversations between commissioners on the one hand, and patients, superintendents, or medical officers on the other, depended largely on the personality of the commissioner; nevertheless, his status was not unimportant, and it would be a great

pity if commissioners who were not members of the Board ceased to hold His Majesty's commission. An error which had been made in the discussions was the assumption that there would be a large reduction in the number of certified cases under care. The provision of temporary treatment was not going to reduce the number of persons ultimately requiring certification by more than 15 per cent.

Dr. W. A. Potts agreed that mental disease and mental deficiency must be a branch of public health, but that did not mean that the two forms of mental disorder could be treated in the same institution. He could not agree that mental disease could often be attributed to a single cause. There was nearly always some psychological factor in addition to many physical factors. He thought that all child guidance clinics should ultimately be linked up with the school medical service, but in some cases it might be advisable to have an independent clinic in the first instance. If the work were to be part of the school medical service it must be carried out on a very comprehensive scale, and there were at present very few workers competent to undertake child guidance. He cordially agreed with Dr. Ash about the dangers of specialisation; nobody could deal with mental disease unless he had had a thorough all-round training, for every kind of treatment might be wanted on occasion. The narrow specialist was, as a rule, quite ineffective.

Dr. Potts described the evolution of the Hallam Hospital at West Bromwich from an ordinary poor-law hospital with one non-resident medical officer and less than 20 trained nurses, as it had been five years ago. Now it had four resident doctors and seven visiting specialists, an up-to-date theatre, a bacteriological laboratory, one of the best X ray rooms in the country, and every kind of equipment. In the old days patients entering the observation wards had almost all been certified or drafted into the house as senile demented. Last year—excluding mental defectives and senile cases over 70 years of age—49 per cent. of those admitted had been discharged improved and only 7 per cent. certified. Mental disease and mental deficiency were absolutely distinct. Mental defect was an inborn condition characterised by abnormality of the brain cells and cure was impossible; the essential treatment was training. Every case of mental disease, on the contrary, should be looked upon as curable if taken early enough. The two conditions required different types of medical officer. Medical students received an absolutely inadequate training in mental disease and none at all in mental deficiency. He had asked a number of young practitioners what they knew about mental defect; while most of them had heard of it, none of them had ever seen a case or knew anything whatever about it. To this, of course, school medical officers were an exception. Yet mental defect was on the increase and its incidence was greater than that of mental disease. It was sure to increase as long as birth control was taught to the healthy and not to the defective, the alcoholic, and the improvident.

Since the passing of the amending Act it was no longer necessary to prove the existence of mental defect from birth. It had therefore become possible to certify cases of epilepsy and encephalitis lethargica which had developed during adolescence. The serious danger thus arose of a tendency to wait until these cases became certifiable instead of treating them. There was a widespread opinion that encephalitis lethargica was not amenable to treatment because serious lesions had been found in the brain in fatal cases. It by no means followed that all cases had these lesions, and in fact encephalitis lethargica, if taken early enough, could be cured by energetic treatment. Dr. T. C. Graves had even succeeded in curing cases of five years' standing.

After a brief discussion, in which Dr. C. T. MAITLAND, Dr. T. W. ILLI, and Dr. BINNIE DUNLOP took part, Dr. ASH replied.

EDINBURGH OBSTETRICAL SOCIETY.

At a meeting of this Society held on March 12th, with Dr. H. S. DAVIDSON, the President, in the chair, Dr. LEITH MURRAY (Liverpool) read a paper on

MYOMECTOMY: A RECORD OF 151 CONSECUTIVE CASES.

Myomectomy, said Dr. Murray, was not yet generally done as frequently as it should be. Conservation in gynaecology, although it could be overdone, was an excellent feature of our modern work. Women were marrying at a later age than formerly, and their uteri therefore were more likely to contain fibroids. He proposed to demonstrate statistically that: (1) numerous fibroids (the largest number he had removed was 11) could be taken from the substance of the uterus as safely as the uterus itself could be removed; and (2) after-results as regards comfort, menstrual function, and safe fertility were almost always satisfactory. Married women in the late thirties or early forties should not, he said, be submitted to hysterectomy merely because they had been sterile for years. He did not think it right to interfere in any radical way with the natural probabilities of married life even in women with several children provided that the fibroids necessitating interference could be removed with moderate ease. To broaden his survey he had included 60 cases in the non-pregnant woman, of most of whom later information was available. In any statistical survey cases of myomectomy in the non-pregnant should, he said, be separated from those carried out during pregnancy. The two operations were different in character and conduct; in the former an attempt was made to remove every fibroid. Of 137 cases of fibroids operated on in the non-pregnant state fibroids of appreciable size were in each instance "dug out" of the musculature of the uterus; all intraligamentary fibroids were excluded. Neither degeneration (of any degree), nor infection (a very rare complication), was any real barrier to operation. In the operation itself he laid special stress on hemostasis. Mechanical or elastic clamps were unnecessary and there was no need to reduce the resulting uterine mass by trimming or excision; involution occurred just as well and as quickly without. Examination at the end of three months showed that the uterus was normal in size and shape whatever its outline was at the end of operation. He recommended exploration of the uterine cavity in all cases where hemorrhage was a symptom.

Dealing with a series of 137 cases of myomectomy in the non-pregnant, for three and a half years, ending December, 1929, he had, said Dr. Murray, carried out 1 myomectomy to 2.8 hysterectomies for fibroids; for the preceding two and a half years the relationship had been 1 to 3.7. Only one case had ended fatally by embolism (0.73 per cent.), whereas his mortality for hysterectomy for fibroids was 1.5 per cent. Two cases of recurrence had been observed and in one of these the uterine cavity, which four years later contained a fibroid polyp, had been explored at the original operation. Of the first series of 60 cases, 35 women under the age of 42 had had a reasonable chance of pregnancy, and of these 34.3 per cent. had had one or more pregnancies since the operation. The latter series of 77 cases had already produced, in 49 possible cases, 22.4 per cent. of pregnancies. For the total of 137 cases up to the end of 1929 the proportion of pregnancies was over 27 per cent. Many cases of acute necrobiotic degeneration could, he thought, be tided over the danger period by repeated doses of morphia.

Of ten cases operated on during pregnancy, six went to full term or viability, three miscarried within 24 hours—probably inevitably—and one died as the result of an injudicious operation carried out on a diabetic. Five cases associated with a diagnosis of intra-uterine death (three, strangely enough, proving to be hydatid moles) all did well, and two of

them had a further pregnancy. Of two cases at full term with irreducible obstruction, one case was easily delivered, by Cæsarean section, of a living child, and four fibroids, the largest a red intramural fibroid the size of a fist, was removed. The other died of a low-grade peritonitis, six days after a Cæsarean section with an extensive myomectomy; the latter did not appear to have contributed to the fatal result.

Dr. Murray concluded by reaffirming his opinion, expressed in 1925, that myomectomy was an operation of less difficulty and danger than was supposed, was available in a large percentage of cases of women of child-bearing age, and should in such circumstances be preferred to hysterectomy.

DIAGNOSIS OF PREGNANCY.

Dr. EDWIN ROBERTSON read a paper based on the work of the pregnancy diagnosis station at the University Department of Animal Genetics. The Aschheim-Zondek test is simple, involving only injection of mice with urine, and later a naked-eye examination for the presence of blood-filled follicles in the ovaries—the *Blut-punkt* of Aschheim and Zondek. Microscopic examination of the ovaries shows that the action of the pregnancy urine is one of maturation. The comparatively massive dosage used in the test probably deranges the maturation processes involved, thus producing the atypical hæmorrhages seen in the follicles. The ovary-stimulating factors in the pregnancy urine are similar to the ovary-stimulating factors which can be extracted from the placenta, not only in the type of reaction produced in the ovary—i.e., maturation—but also in being destroyed, precipitated, and dissolved by the same agents. Therefore the active substances in the urine are probably only products of the placenta excreted for some reason as yet undefined. Hence a positive test is a placental sign and means, at least, the presence of placental elements. Now the function of the ovary depends upon extra-ovarian factors which are for the most part situated in the anterior lobe of the pituitary, and it has been shown that the ovary-stimulating powers of the placenta are similar to those of the anterior lobe of the pituitary. Wiesner has explained this mutual relationship in a most convincing way. "The internal secretion of the ovary is necessary for the inception and maintenance of the conditions of pregnancy, and the stimulus of the placental hormones is required for the continuation of the ovarian function beyond the initial phase which occurs under pituitary influence." This particular rôle of the pituitary and the activity of the placenta are reflected in the urine of pregnancy; urine which will produce ovarian maturation is therefore probably from a pregnancy.

Of the total 907 tests hitherto made, 479 have been controlled and found correct. Of these, 288 were positive and 179 were negative. Thirteen additional cases were labelled incorrect, but four of these were so designated through a misinterpretation of the test result by the clinician. Nine incorrect results out of 479 tests gives a 98 per cent. degree of accuracy. The test is also useful in detecting the presence of active placental elements and also hydatidiform mole and chorion epithelioma. Incomplete abortions, ectopic pregnancies, missed abortions, and cases of retained placenta have all conformed to the rule that if the elements present are alive and active then a positive result will be obtained and vice versa. It is thought that both hydatidiform mole and chorion epithelioma are extremely active in the production of the ovary-stimulating substances and that the presence of lutein cysts in association with these conditions is strong evidence in favour of this view.

Lysozyme.—Dr. D. Nabarro writes that in his remarks made at the meeting of the Medical Society for the Study of Venereal Diseases (THE LANCET, April 5th, p. 753) it was not Mr. Percy Flemming to whom he referred as having discovered and named the material now known as lysozyme, but Mr. Alexander Fleming of St. Mary's Hospital. It was Prof. Rominger, of the Children's Hospital at Kiel, who was quoted as favouring injections of sterilised milk.

Reviews and Notices of Books.

SURGICAL DIAGNOSIS.

By American Authors. Edited by EVARTS AMBROSE GRAHAM, A.B., M.D. Bixby Professor of Surgery, School of Medicine, Washington University, St. Louis. London: W. B. Saunders Company, Ltd. 1930. In three volumes. £7 10s. per set. Vol. I. Pp. 919. Vol. II. Pp. 871.

THIS work, of which two volumes have been issued, promises to be a credit to American surgery. Though the title of "Surgical Diagnosis" might have excused a somewhat narrow outlook, the editor has wisely interpreted his task in a broad sense. The articles in the first two volumes deal with ætiology, pathology, and to some extent with treatment in so far as they illuminate diagnosis, and while due stress is laid on the clinical aspects, laboratory methods are not neglected. The list of distinguished surgeons who contribute to the work prepares the reader for a surgical feast, and his expectations are realised. The first volume is devoted to the consideration of wounds, infections, post-operative complications, diseases and injuries of the vessels, bones, muscles, fasciæ, and tendons, including fractures and dislocations, and so is in considerable part orthopædic in character. The two major sections are by Dr. Leroy Charles Abbott and by Dr. John Albert Key. Both are excellent; that by Dr. Abbott provides a résumé of orthopædic surgery which could hardly be bettered, either in clarity of exposition or inclusiveness. The section on fractures, while admirably serving its purpose, suffers from the necessary omission of those questions of treatment which constitute the more fascinating aspects of this branch of surgery. The article on diagnosis of joint disease and injury by Dr. Nathaniel Allison deals with a very difficult subject clearly and concisely, while the name of Dr. Kanavel as joint author of the section on infections of the hand is sufficient guarantee of its quality. The illustrations throughout this volume are excellent, with the possible exception of some of the X rays of abnormal conditions of the spine; some skilful retouching of the negatives would have improved the teaching value of these.

The second volume opens with a chapter on gynecological diagnosis, and this is followed by sections on the skin, face, neck, and thyroid, the alimentary canal from stomach to colon, with sections on the spleen, on hernia, and on acute abdominal emergencies. The chapter on gynecology suffers from compression. The diagram of air distension of the tubes produced as Fig. 576 is hardly worth a further reproduction as Fig. 589. No reference in the text is made to the illustration of radium therapy (Fig. 540), and it is hardly good enough to justify its inclusion. On the other hand, a few more illustrations would have been helpful in the section on the face and jaws, particularly in regard to diseases of the tongue. The same criticism applies to the chapter on diseases of the neck which is entirely unillustrated. The alimentary canal receives clear and careful treatment, but it seems unfortunate that the sections on liver, gall-bladder, and pancreas, which presumably are relegated to Vol. III., could not have been discussed with the remainder of the digestive tract.

While congratulating Dr. Graham on the way he has carried out his editorial duties, we would make two suggestions. The first is that his own bracketed comments or interpolations, valuable as they are, would be better incorporated in the article by agreement with his contributor. The second is that the bibliographies at the end of each section should be rearranged on a uniform plan, to include the quoted authorities in the text, the unnumbered lists of papers and the references in foot-notes.

These volumes are in themselves a fine achievement, and will make all those who come across them eager to possess the completed work.

DISEASES OF THE EYE.

Sixth edition. By Sir JOHN HERBERT PARSONS, C.B.E., D.Sc., F.R.C.S., F.R.S., Ophthalmic Surgeon, University College Hospital; Surgeon, Royal London (Moorfields) Ophthalmic Hospital. London: J. and A. Churchill. 1930. With 21 plates and 318 text-figures. Pp. 678. 18s.

THIS text-book from the pen of an acknowledged authority can be safely recommended to students and practitioners. Though recent advances are incorporated the author limits his book to practically its former size. The slit lamp, although it has produced no revolution in ophthalmology, has already proved itself of service in practical diagnosis, and a new diagram shows how the minute structure of the lens can be illuminated by this lamp. Another diagram shows how a foreign body in the cornea can be exactly located with its help. The importance of the presence of solid particles in the aqueous which could not be detected without the slit lamp is also stressed. Other useful additions are diagrams explaining "Rönne's step" in the perimetric diagnosis of glaucoma, a figure showing senile marginal atrophy of the cornea, and several figures taken from drawings or photographs of the late Mr. Coats (for years pathologist to Moorfields) illustrating retinal vascular degenerations and the atrophic nerve in tabetic optic atrophy. The account of the treatment of wounds of the cornea and sclera is somewhat fuller than before.

PRACTICAL PSYCHOLOGY AND PSYCHIATRY.

Sixth edition. By O. B. BURN, M.D., late Medical Director, Oak Grove Hospital, Flint, Mich. Philadelphia: F. A. Davis Company. 1930. Pp. 378. \$2.75.

THIS small book is evidently written by an experienced psychiatrist, whose psychology is of a practical sort. The opening chapter, which is mainly a free paraphrase of Bertrand Russell, will not appeal to the English reader, but after skipping this he will find the rest well arranged, adequate while avoiding unnecessary elaboration, and full of sound practical advice. The psychology is that of the old "faculty" brand, but is clearly put and well related to the disorders of the faculties occurring in mental disease. The chapter on aberrations in the sphere of sex is curious in its selection of material and fails to mention masturbation at all. In that on definition and causes of insanity the author leans to the physiogenic and ignores the psychogenic side; he includes vicious habits as causing 25 per cent. of cases, whereas most people would regard these as results of the disorder of mind. The descriptions of syndromes are excellent; occasional trifles may arouse critical comment—e.g., the suggestion that dementia præcox may be caused by typhoid, and reference to the "syphilitic bacillus"; nor would most people regard adolescence as the period from 25–35 years of age. The assertion that "paranoia and pellagrous insanity" are mental defects from congenital causes or arrest of development in infancy must surely be an error of proof-reading, some transposition of matter having doubtless occurred. The chapter on management of insanity from a medical standpoint is sound, practical, and reliable; that from the nursing standpoint excellent as to general principles; while the final sections on mental hygiene, though brief, emphasise all essential points.

The author prefaces the book on the title page as being "for use in training schools for attendants and nurses and in medical classes, and as a ready reference for the practitioner." In this country we should consider it too theoretical to be more than an interesting addendum to a handbook for training nurses; the medical student will find it valuable illumination for his course in psychological medicine; but it is the general practitioner and the newly joined junior medical officer in a mental hospital who will appreciate

it to the full. To complete the information required by these readers a chapter on legal matters and procedure for certification or other conditions required by American law in the management and care of mental patients might be added.

NOTABLE BRITISH TRIALS.

The Trial of Browne and Kennedy. Edited by W. TEIGNMOUTH SHORE. London: W. Hodge and Co. 1930. Pp. 218. 10s. 6d.

Browne and Kennedy were hanged two years ago for the murder of Police Constable Gutteridge. The chief legal interest lay in the question whether the two should be tried jointly or separately. This is a question for the discretion of the judge at trial; if he exercises his discretion judicially and no injustice results, no other court will interfere. As usual the Court of Criminal Appeal had no ground for criticising the handling of the case by so experienced a judge as Mr. Justice Avory. Kennedy had incriminated Browne in a remarkably full statement to the police. Joint trial could be said to have embarrassed the defence. When this point was taken on appeal against their conviction, the Lord Chief Justice ridiculed the doctrine that, if two persons of bad character commit a crime together, they must never be tried jointly because the character of one may hurt the other. The trial is devoid of medical interest save for the fact that the murder was committed while the criminals were in possession of a motor-car stolen from a doctor's garage. The car had contained certain medical appliances, subsequently discovered in Browne's premises; his explanation of how he came by them was unconvincing. The murderers carelessly left a spent cartridge case in the car when they abandoned it a few hours after the theft. The gunsmith's evidence identified the pistol which had fired the shot. Apart from this important advance in detective science, the trial was scarcely more notable than any other trial for murder.

Browne and Kennedy carried firearms, intending to use them to avoid capture. They shot the constable dead while doing his duty; further shots were callously fired into his eyes. Had these outlaws not been brought to justice there would have been great public uneasiness. Could a referendum have been taken on the question whether their punishment should be death or a long term of imprisonment, it might have revealed strong support for the retention of capital punishment.

BLOOD GROUPING IN RELATION TO CLINICAL MEDICINE.

By LAURENCE H. SNYDER, Sc.D., Associate Professor of Zoology, North Carolina State College, Raleigh, N.C. London: Baillière, Tindall and Cox. 1929. Pp. 153. 22s. 6d.

THIS book represents the only attempt in the English language to envisage the present state of knowledge in regard to the blood groups. It contains little that is entirely new, but is of value in that it brings together for the first time in English a large number of facts until now only available in scattered articles in various journals, many of them in foreign languages. Nothing appears to have escaped the author and the bibliography is monumental. In common with most recent workers on the subject he regards it as practically established that the whole constitution of the blood groups can be explained by the postulation of the original agglutinogens A and B of von Dungern and Hirschfeld; the description of the various agglutinogens which filled the literature on the subject a year or so back he regards as having had their roots in errors of technique. He regards the view of Bernstein on the inheritance of the groups (based on the conception of the triple allelomorphism of the dominants A and B and the recessive O) as adequate to meet all the

requirements of the situation as at present known. All the author's own observations on the subject, and they are numerous, are in conformance with this hypothesis. Chapters IX., X., and XI., dealing with the inheritance of the groups, are particularly valuable.

JOURNALS.

JOURNAL OF PATHOLOGY AND BACTERIOLOGY. Vol. XXXIII. No. 2. Pp. 233-495. April, 1930.—The number is dedicated to Prof. W. H. Welch, an honorary member of the Pathological Society of Great Britain and Ireland, on the occasion of his eightieth birthday on April 8th, 1930.—Primary Malignant Intrathoracic Tumours, by J. Maxwell (London). Of 239 tumours at St. Bartholomew's Hospital, 184 were primary bronchial carcinomata; it is suggested that the oval-celled carcinoma arises from the basal layers of the mucosa. Some of the mediastinal tumours are sarcomata arising in lymphatic glands.—An Embryonic Tumour of the Liver containing Striated Muscle, by H. L. Sheehan (Manchester). In a girl of six the liver contained a number of papilliferous cysts, one of which became malignant.—An Unusual Case of Diffuse Tuberculous Infiltration of the Myocardium, by J. G. Thomson (Aberdeen).—Antivaccinal Serum: Evidence for Slow Union with Virus in vitro, by C. H. Andrewes (London). In the body the antibody of antivaccinal serum is effective almost at once in preventing the effect of virus; in vitro the virus is neutralised only after several days.—Specific Antibody Absorption by the Viruses of Vaccinia and Herpes, by W. Smith (London). The viruses absorb their corresponding antibodies.—Multiple Malignant Neoplasms, by J. W. Orr (London). In 7207 autopsies, 1046 of which showed malignant disease, there were eight in which two independent malignant tumours were present. There is no evidence that one tumour has any influence on the development of another.—Fatal Granulomatosis of the Central Nervous System due to a Yeast (Torula), by F. B. Smith (Harrogate) and J. S. Crawford (Ilkley). A woman of 31 with generalised blastomycosis, the lesions apart from the nervous system being inconspicuous.—Invasion of Epidermis by Carcinoma, by J. S. Dunn (Manchester). A mucinous carcinoma at the anus growing into the epidermis and resembling Paget's disease of the nipple.—Tissue Culture in the Study of Immunity to Herpes, by C. H. Andrewes (London). Herpes virus multiplies and forms inclusive bodies in tissue cultures of rabbit testis and may be carried on through serial cultures. It grows equally well in tissue cultures made from the testes of immunised rabbits. Immune serum prevents infection of the cells but has no influence after infection has occurred.—The Inheritance of the Blood Group Factors, by G. K. Kirwan-Taylor (London). The examination of 250 fathers, mothers, and babies supports Bernstein's theory that there are three allelomorphs, A, B, and O.—Two Cases of Foetal Rickets, by J. Preston Maxwell (Peking). Two clear cases in children born from mothers with severe and untreated osteomalacia. H. M. Turnbull (London) reports that the bones of one of the cases show the changes of rickets combined with those of Barlow's disease.—The Role of the Spleen in the Production of Antibodies, by W. W. C. Topley (London). Experiments suggesting that the spleen is concerned in the elaboration of antibody or of some precursor.—The Toxicity of Irradiated Ergosterol, by J. B. Duguid, M. M. Duggan, and J. Gough (Cardiff). Large doses do not produce loss of weight, arterial calcification, &c., if the rats are fed on an ordinary mixed diet; positive results are obtained with a synthetic diet rich in calcium.—Epithelial Proliferation in the Lung of the Rabbit brought about by Intrapleural Injection of Solutions of Electrolytes, by J. S. Young (Leeds). The reaction to salts is determined almost exclusively by the cation. Trivalent metals are more effective than divalent and these than monovalent. Among the heavy metals capacity of

cause cell growth is inversely proportional to solution pressure.—Spinal Metastases in a Case of Cerebral Glioma of the Type known as Astrocytoma Fibrillare, by D. S. Russell and H. Cairns (London). Pin-head metastases in the subarachnoid space.—The Genus *Willia*, by J. F. D. Shrewsbury (Birmingham). A systematic account of three species of this genus of yeasts.—A Transplantable Melanoma of the Mouse, by H. E. Harding (London), and R. D. Passey (Leeds). Arose in skin of ear. A large proportion of the cells in the tumour are extraneous phagocytes stuffed with melanin.—Intravital and Supravital Staining: the Cellular Reactions following Mild Irritation of the Peritoneum, by D. F. Cappel (Glasgow). Consult the original for details.—Acute Disseminated Encephalomyelitis as a Sequel to "Influenza," by J. G. Greenfield (London). Two cases following vague febrile attacks, one fatal in five days, the other in seven weeks. The perivascular demyelination and other lesions are of the same type as those found in the encephalitis which sometimes follows small-pox vaccination or measles. This "post-vaccinal encephalitis" is a disease per se.—Experimental Vaccinal Encephalitis in the Monkey and the Rabbit with Special Reference to the Problem of Encephalitis following Vaccination in Man, by E. W. Hurst and R. W. Fairbrother (London). The essential lesion of experimental infection of the brain with vaccinia virus is a fibrinous hæmorrhagic and polymorphonuclear meningitis, completely different from post-vaccinal encephalitis.—The Reaction of the Central Nervous System to Vaccinia Virus by J. McIntosh and R. W. Scarff (London). The lesions produced in the brains of rabbits by virulent strains of vaccinia virus are essentially the same as those found in post-vaccinal encephalitis in man.—A Primary Carcinoma of the Kidney, by I. Gray (Aberdeen). Diffusely infiltrating the organ.—A Specimen of Implantation of Secondary Carcinoma within the Intestines, by J. H. Teacher (Glasgow). About a hundred small tumours of spheroidal-celled carcinoma in the loose areolar tissue of the submucosa of the small intestine, probably from a carcinoma of gall-bladder.—The Gonococcal Complement-fixation Test: Improvements in Technique, by I. N. O. Price (London). Gonococci dissolved in alkali and precipitated by alcohol yield a good preparation by which the time taken by the test can be materially reduced.

Reports and Analytical Records.

CHELTOVA TONIC FOOD BEVERAGE.

(CHELTINE FOODS CO., CHELTENHAM.)

THIS food, which is of a light chocolate colour, is prepared for use by mixing two spoonfuls to a breakfast cup with hot milk and sweetening according to taste. It is intended for occasional or regular use, and it may be regarded as an appropriately balanced food material. It claims to be rich in vitamins A, B, and D, and to contain C. On analysis the following results were obtained:—

	Per cent.
Carbohydrates	59.51
Fat	12.47
Protein	17.50
Mineral matter	5.06
Moisture	5.40

The carbohydrates are derived, inter alia, from germinated grain and from cocoa; there is no evidence that starch other than that natural to the cocoa is present. The mineral matter contains 0.41 per cent. of phosphorus (P_2O_5) and 0.4 per cent. of iron in a soluble state. Lecithin and an active diastase are also present.

THE LANCET.

LONDON: SATURDAY, APRIL 19, 1930.

POST-GRADUATE MEDICAL EDUCATION.

LAST week there was published by the Ministry of Health a document of the highest significance in the cause of medical education, and one, moreover, which indicates that a course advocated, and often vehemently demanded, for the past 20 years, is now to be taken. A central scheme of post-graduate education in London has passed from the stage of hope to that of accomplishment, and when the movement took place it took place quickly. A committee appointed in the year 1925 by Mr. NEVILLE CHAMBERLAIN, then Minister of Health, "to draw up a practical scheme of post-graduate medical education centred in London," have made their Report, and the recommendations are both unanimous and eminently workable. We summarise this Report briefly elsewhere, and it should be noted that immediately upon its appearance an announcement was made on the part of the Ministry of Health accepting the findings of the committee. For Mr. GREENWOOD said that the Government, in agreement with the views of the committee, would grant £250,000 for building and equipping a medical school as an integral part of a post-graduate centre in London, to be placed at the Hammersmith Hospital, Wormwood Scrubs. This hospital of 400 beds became the property of the London County Council at the beginning of this month, under the terms of the Local Government Act; the Council's co-operation in the development of the scheme may be relied upon, as may that of the University of London.

The necessity of providing post-graduate medical education in London has been insisted upon for years wherever and whenever medical education has been under discussion, but active work to secure that end, though for long in motion, has had little material result, however fair the early promises. Hence to many who have had the cause of medical education at heart it may seem almost incredible that a plan has arrived, ready for working, under which obstacles, hitherto fatal to anything like a general scheme of London post-graduate teaching, have suddenly faded away. The early work of JONATHAN HUTCHINSON and the Medical Graduates' Clinic, the later activities of the Fellowship of Medicine, subsequently amalgamated with the Post-Graduate Medical Association, have all appeared fruitless because, for this sound reason or that, a centre at which was provided even the minimum of what was necessary could not be established. But these pioneer efforts have had their part in bringing about the position which has now been reached, and this should be a source of gratification to many who hitherto have experienced only disappointment in their various efforts. The initial step forward was taken when Dr. CHRISTOPHER ADDISON, the first Minister of Health, set up the Post-Graduate Medical Committee, which sat under Lord Athlone, and issued a report some nine years ago. This was a strong committee, and its appointment was an official recognition of the fact, over and over again insisted upon by those in whose hands the conduct of medical practice lay, that the sound medical curriculum

which we possess—this no one denying—needs in these days post-graduate additions, revisions, and refurbishings, if it is to play its due part in the maintenance of national health. It had been seen that in the conduct of medical practice post-graduate education will soon become an integral part, as was indicated by the growing habit of taking study leave; and while post-graduate classes became recognised as a necessity for officers in the Services, those familiar with the working of medical practices at home knew that the family practitioner needed opportunities for supplementing his scientific equipment every bit as much as his colleagues directly in the service of the State. The findings of the Athlone Committee were in no sense a revelation, when the committee put on record the outstanding needs, first, for the establishment in London of a central school of hygiene, and, secondly, for a post-graduate hospital with a medical school attached. Such were the conclusions of those who had taken part already in long discussions on various aspects of the question, and who gave evidence, many of them, before the Athlone Committee. But, alas, the conclusions of these debates always appeared to demand the unattainable; and now, suddenly, both needs have been met. For since the issue of the Athlone report the London School of Hygiene and Tropical Medicine has been established, while more recent legislation has made possible the acquisition of a general hospital to be applied with an attached school, to post-graduate needs. During the long years of discussion it came to be generally admitted that no progress in a post-graduate scheme of medical education for London would ever be made until a hospital with a sufficient number of beds could be obtained to which a medical school could be attached, where training could be given fitted to the needs of the graduate, since graduate and undergraduate medical teaching cannot be made to run hand in hand at the same institution. The hospital has been found, and so have the means for its proper development and adaptation.

Thus far very good, but much cause for thought remains; there is need for definition of the scope of the work ahead if just judgments are to be formed of the policy that may ensue in respect of many things. For example, the selection of the officiate is going to exercise many minds. Post-graduate education is a term that covers much, especially when the efforts represent what a Nation with wide possessions feels moved to do in its Metropolis. Post-graduate education is needed as much by the family practitioner as by the officer in the Services, and as much by those at home as those abroad; while, with every desire that London should take a rightful place as an international centre of medicine, we must not wish to depend either on the goodwill or on the fees of strangers for the success of a new London post-graduate school. Hence it is a varied clientele whom the school should serve, and serve equally well, and proportionately to the different demands on its activities and resources. Instruction, therefore, of very different sorts may be needed, and a personnel of very different sorts may be looked for in the teaching staff. A salary that could reasonably be offered to a good teacher along certain lines of post-graduate training could not be offered to another and more widely known man, and though the latter would be the teacher whom some of the adherents to the school would expect to hear, he might none the less be but ill-fitted for an educational appointment. Perhaps a rota of teachers of the needed learning and variety might be obtained from the undergraduate teaching centres; the obstacles here are obvious, but need they be unsurmountable?

This is but an example of the matters which remain to be dealt with. They are details, and only details by comparison with the arrival of a great central scheme, but there will be room in their adjustment for the display of adequate leadership, and it is not too soon to give them consideration.

PULMONARY ASBESTOSIS.

THE introduction of that extremely useful substance asbestos into industry has unfortunately given rise to a new occupational risk and to yet another form of chronic pulmonary fibrosis. The material has in one form or another been known since the days of Greek and Roman civilisation—the ancient writers refer to it as “unquenchable stone”—and CHARLEMAGNE is said to have had a table-cloth made of it, which was cleansed by throwing it in the fire. In earlier days the hornblende variety of asbestos was often referred to as amianthus. Sir THOMAS BROWNE, the author of *Religio Medici*, in one of his poems sighs that he might have amiantine toes which would not suffer from the gout. The indestructibility of asbestos has no doubt been the primary reason for its introduction into trade processes; asbestos will resist great heat, strong acids, and alkalis, whilst owing to its fibrous structure certain varieties of it can be carded and spun like a textile. A report¹ just published by the Home Office deals with the effects of asbestos dust on the lungs and on the dust suppression in the asbestos industry, and is written by Dr. E. R. A. MEREWETHER and Mr. C. W. PRICE, respectively medical and engineering inspector of factories. Dr. MEREWETHER'S report is based upon data obtained in an extensive investigation made during 1928 and 1929, initiated by the Home Office, following the discovery of non-tuberculous fibrosis in the lungs of an asbestos worker, of sufficient severity to necessitate treatment in hospital. Prior to this the Home Office had knowledge of only two deaths in which the inhalation of asbestos dust was a contributory cause; a survey of the industry in 1910–11 had not revealed any serious hazard. The well-known triad—exposure to dust, fibrosis of the lungs, and high mortality-rate from pulmonary tuberculosis—has long been recognised in industrial processes involving the use of free crystalline silica, but, as Dr. MEREWETHER remarks, the fact that a serious, even fatal, degree of fibrosis can be produced by other dusts has not been generally appreciated. A peculiar feature of the fibrosis produced by asbestos dust is the occurrence in the sputum or lung-juice of bodies, described by Prof. MATTHEW STEWART, which have a curious resemblance to a minute crustacean.² These consist, as BURTON WOOD and GLOYNE have shown, of a series of discs around a central spicule of asbestos.

The manufacturing processes fall into one of two groups according as they employ (more or less) pure asbestos and asbestos along with other dusty substances. The former group has been the subject of this inquiry on the ground that the effect of asbestos dust alone must be worked out before the complicated factors can be assessed. The population at risk in this group of the industry is not exactly known, but is estimated at 2200. A certain amount of selection was used in the examination, new-comers and long-time workers being chosen. The men examined were with one exception at work on the day of examination; their number (excluding 11 cases who had previously worked in other dusty occupations)

was 363, or 16.5 per cent., of the estimated total workers in the industry. Of these, 95 (or 26.2 per cent.) showed a diffuse fibrosis of the lungs attributable to the inhalation of dust; 21 others had precursive signs of the disease. In 133 cases radiograms were made; 62 of these showed definite diffuse fibrosis, 25 were only suggestive. Dr. MEREWETHER is careful to emphasise the fact that only a proportion of the workers have been examined and that it would be unfair to assume that roughly 1 in 4 asbestos workers have fibrosis; the group examined was loaded with a high proportion of men who had been five years or more in the industry. The actual figures were these. There were no cases of fibrosis among those who had been employed less than 4 years, 36 cases in those employed from 5–9 years, 27 cases in those employed 10–14 years, 15 cases in those employed 15–19 years, and 17 cases in those employed over 20 years. Considering the relation of fibrosis to age the largest number of cases were found in the age-groups 30–39 and 40–49; Dr. MEREWETHER deduces that the important factor is the length of exposure, and that the age factor is negligible. The difficulties in ascertaining the incidence of fibrosis amongst workers in particular processes seem insurmountable as many processes are housed in one room and workers are transferred from one process to another. But there is clearly a lower incidence and probably a later onset among the spinners as a group than among those who crush, card, or weave asbestos. No evidence was found to indicate that one variety of asbestos is more potent than another in producing fibrosis. Concentration of dust and length of exposure are interdependent factors. For a number of years disablement, it seems, is curiously slight, even more so than in the case of silicosis. This may be due in part to the character of the disease, and in part to the fact that the work is not as a rule strenuous. The affected worker often continues at work with occasional breakdowns from bronchitis until he is aware of shortness of breath upon exertion. A terminal broncho-pneumonia or other acute infection may supervene while the man is still at work; with others there may be a period of invalidism. Particulars are given of ten cases up to the end of 1929 in which an advanced degree of abestosis without tuberculosis was the primary cause of death, nine being verified post mortem. The length of exposure in these cases varied from 9 to 24 years. The rate of progress seems to vary within wide limits. With continued exposure to high concentrations of dust the fibrosis may be fully developed in from seven to nine years; with a lesser the fibrosis may take 15 to 25 years to mature. So far as the available data go there is no special liability to pulmonary tuberculosis amongst asbestos workers.

Preventive measures are dealt with by Mr. C. W. PRICE in the second part of the report. The factories and workshops concerned number at least 160, of which 18 are textile factories. Small premises are the rule. The majority are well-housed and well-ventilated, but there are some open-sided sheds which are difficult to keep clean, and some which are congested with material. The arrangements for ventilation vary much. Dust removal systems where used effect a measure of general ventilation; over-head extracting fans are unsuitable and little used. Extraction by downward displacement has been considered for weaving rooms and Mr. PRICE considers it might, with suitable safeguards, replace the localised exhaust ventilation, although it could not be successful without efficient heating. While very dusty processes are already recognised, he points out

¹ H.M. Stationery Office, Pp. 34. 1s. 3d.

² THE LANCET, March 1st, p. 445, and March 29th, p. 701.

that in processes such as spinning and weaving, in which in other textile trades special methods for dust control are not required, precautions must also be taken in asbestos works. The manufacturers are clearly confronted with the necessity of attaining conditions which will ensure much less dust in the atmosphere than can be tolerated safely in comparable trades not using asbestos. The recommendations in the report include the application of efficient localised exhaust ventilation at dust-producing points; the substitution of enclosed mechanical methods for hand conveyance, and for dusty hand-work generally; the effective enclosure of dust-producing machines and plant; and the substitution of wet methods for dry. Young persons should be excluded entirely from specially dusty work.

STATE MEDICAL SERVICE.

The objects of the State Medical Service Association have been revived in the National Medical Service Association, the constitution of which was adopted last week at a meeting held at the House of Commons by invitation of three medical Members—namely, Mr. SOMERVILLE HASTINGS, Dr. ALFRED SALTER, and Dr. ETHEL BENTHAM. Membership of the new Association is to be open to all registered medical men and women and dentists, to registered medical and dental students, and to others who are in sympathy with its objects. The primary aim is to advocate and make clear to the medical profession and to the public the advantages of a national medical service, and for this purpose it will hold public meetings, publish and circulate literature, and otherwise promulgate its cause. The Association will also take steps to promote and secure legislation giving effect to its objects. In a footnote to the constitution it is stated that a national medical service should include the establishment of a medical service available to all members of the community and providing every necessary form of medical, surgical, obstetrical, dental, and preventive treatment, coordinated as one service under the Ministry of Health. It will be recalled that these were substantially the aims of the State Medical Service Association founded in 1912 with the late Prof. BENJAMIN MOORE, F.R.S., as president, Dr. JANE WALKER as hon. treasurer, and Mr. CHARLES A. PARKER as hon. secretary, the activities of which were overshadowed by the coming of the war. This Association was founded because its promoters felt that the time had come for freeing a large section of medical men and women from the distasteful and incongruous task of assessing and collecting fees for services rendered; in its stead they should be guaranteed an adequate and certain salary during their active years of service, coupled with a system of gradual promotion and followed by a generous pension. Under such a scheme the present hospital system would be placed, it was urged, on a firm financial basis, hospital staffs being properly remunerated and hospital doors opened to all sections of the community. The scheme was frankly described as the organisation of the medical profession as a branch of the nation's civil service. The new Association has, we understand, as yet gone little beyond the drafting of its constitution and acceptance of the principle that an efficient medical service can only be built up if the doctors who are serving in it are allowed a large say in the conditions of service. Its promoters feel that the time has come for the State to accept responsibility not only for certain special affections such as tuberculosis and venereal disease, but for the provision of

efficient treatment for all who require it. There is, however, nothing of the reforming bigot about them, and there is no suggestion of placing all doctors under Government control while improving, from the public point of view, the medical activities of the State.

Annotations.

"No quid nimis."

PATENTS FOR FINE CHEMICALS.

IN summarising the report of the British Science Guild on the British patents system, we commented on it from the point of view of the medical inventor.¹ In a recent address to the Society of Chemical Industry² Mr. F. L. Pyman speaks from the point of view of the manufacturer. He points out that chemical firms incur enormous expenditure when they undertake the research which leads to the preparation of new or improved substances. It is not unreasonable for them to expect a temporary monopoly of the drugs which are discovered through their enterprise. In the absence of a monopoly they have little incentive to market the product. Dakin's solution, for instance, is a valuable antiseptic which is little advertised simply because it was not patented and can be manufactured by anybody. Supposing that a manufacturer prepares all the many possible derivatives of a certain drug which has purgative properties, and eventually finds one which is an efficient purge and is at the same time free from objectionable actions. If he puts this substance on the market under a registered name—the "something brand" of the drug—other manufacturers will speedily market it as the "something else brand." If he sells it disguised as a constituent of an undeclared mixture the medical profession will be prejudiced against it. The only other course open to him is to keep his knowledge to himself and try to find some allied substance with a similar action "new" enough to be patented. Obviously, Mr. Pyman concludes, an adequate system of monopoly patents is essential to the manufacturer as an incentive to research, to the marketing of products, and to the disclosure of processes.

Mr. Pyman welcomes the proposals of the British Science Guild as a means of protecting "biological" products without infringing the ethical code of the medical profession, but is not at all so sure of their value for "chemical" drugs. "Dedicated" patents might well protect such inventions as "quinamil" and thyroxin, but a patent is in effect a reward for disclosure, and the manufacturer cannot be expected to disclaim the reward in the way that the medical research worker is expected to do. If the manufacturer cannot patent the fruits of his enterprise in endowing research he will try to keep his processes secret. Mr. Pyman instances the case of histamine, the activity of which was demonstrated in 1910. Soon afterwards Mr. Pyman devised a new and improved synthesis which was patented by Mr. Wellcome and himself. If the employing firm had been able to obtain only a patent which they could not control they would have had no inducement to allow Mr. Pyman to publish his method, and he feels that the result of substituting "dedicated" for monopoly patents will be to restrain the patenting of improved processes for the manufacture of known compounds, and consequently to hinder the publication of scientific work. Moreover, as he points out, chemical inventions often proceed step by step, and the manufacturer who cannot obtain a monopoly for his drug will endeavour to protect some intermediate product essential for its synthesis. He advises all interested parties to scrutinise very carefully the proposed changes in the patent system before they are allowed to pass into law.

OPHTHALMOLOGY IN EGYPT.

THE third annual report of the Giza Memorial Ophthalmic Laboratory, recently published, contains, in addition to a summary of the work for the year 1928, a brief account of the laboratory itself. It was founded as a memorial to the men of the Egyptian Labour Corps and Camel Transport Corps who gave their lives while serving with the armies of the British Empire during the Great War. The funds for its erection were voted in 1921 by the Imperial War Graves Commission in London, and with the approval of the Egyptian authorities, the scheme of Mr. A. F. MacCallan, at that time Director of the Ophthalmic Section of the Department of Public Health, was adopted, for the erection of a laboratory for pathological study and research in connexion with diseases of the eye. The Egyptian Government having granted a further sum for equipment, the laboratory was opened in 1925 on part of the site given by the Egyptian Government for a new Ophthalmic Hospital at Giza, which was itself opened in 1926, since when the two institutions have worked side by side, it being arranged that the Director of the Laboratory should be a European ophthalmic surgeon who should also be an honorary surgeon in the adjoining ophthalmic hospital, and that he should be assisted by a European pathologist and two Egyptian doctors specially trained in ophthalmology. The report, written by the Director, Mr. Rowland P. Wilson, of the work done in 1928 includes accounts of clinical and pathological cases of interest, and is well illustrated. Much attention is devoted to trachoma which affects as many as 90 per cent. of the Egyptian population, but no new light is thrown on its pathogenesis. The results of different methods of treatment, both of trachoma and of acute purulent ophthalmia, are compared; injections of milk appeared materially to shorten the duration of the acute stage. Both in this publication and in the *Bulletin* of the Ophthalmological Society of Egypt for 1929 the value of subconjunctival injections of phenolaine in the treatment of corneal nebulae is spoken of, a method first employed in India by V. Nesfield. A number of cases of proptosis from tumour and other causes are also described in the *Bulletin*, which affords evidence of sound ophthalmological work.

A SANATORIUM PHYSICIAN ON THE STETHOSCOPE.

IN his report for 1929 Dr. J. Gravesen,¹ medical superintendent of Vejlethjort Sanatorium in Denmark—that institution in which so much pioneer work has been done since its foundation by Prof. Saugman 30 years ago—takes stock of the present state of the tuberculosis problem as far as the early diagnosis and most effective treatment of pulmonary tuberculosis are concerned. It really is amazing what a change has come over this scene during the last few years, and Dr. Rip-van-Winkle after sleeping for a decade or so would now wake up to quite a new world. It is not new only in that ephemeral world of treatment, in the durability of which none of us trusts, but also in the field of pathological anatomy in which some of us have been tempted to find truths and facts more lasting than brass. Only a decade or two ago the first deposits of tubercle in the lung were to be found in the apex, above the clavicle. Now they have shifted further down; and it is in the early infiltration demonstrable by the X rays, below the clavicle, that the radiologically-minded, radiographically-trained, pathological anatomist now seeks the beginning of things tuberculous in the lungs. The practitioner may ask: "What concern is it of mine, this new vogue?" The answer to this question by sanatorium specialists like Dr. Gravesen is more or less as follows: Thanks to the understanding and perfecting of serial skiagrams of the lungs, it is now

possible, if a specialist in this field is employed, to detect the signs of incipient pulmonary tuberculosis much earlier than was the case only a few years ago. Phenomena which less than ten years ago were regarded as early signs of tuberculosis are now considered as late signs thereof. The first onset of the disease, the stage in which there is an early extension of the infection in a limited area of the lung (the early subclavicular infiltration) is often, probably in most cases, mistaken for a "cold," influenza, or the like. After invaluable time has been lost, and the early and most curable stage of the disease has been irrevocably passed, the patient is put on the waiting list of a sanatorium, whose medical superintendent ultimately examines him and finds advanced disease in a case "sent for diagnosis, query early tuberculosis." Dr. Gravesen writes:—

"In the face of this tragic situation, we may derive help from recent gains in our knowledge which emphasise unequivocally the fact that the earliest beginnings of pulmonary tuberculosis are associated with insignificant and often quite negative stethoscopic signs . . . the stethoscopic examination, even when it is carried out with all the finesse which, in the course of time has been devised for its rescue, is an exceedingly imperfect device which must of necessity be supplemented by serial skiagrams, supported by fluoroscopy, if it is to be a guide to the detailed diagnosis."

Be it noted that this is not the opinion of a specialist who has studied no other special branch of medicine than radiology, and who despises other means of diagnosis, such as auscultation and percussion, largely because he has not practised and mastered them. It is the opinion of a sanatorium physician who, though specialising in radiology, has perforce had to familiarise himself with every known test of tuberculosis. Dr. Gravesen does not hesitate to describe the outcome of recent advances in our knowledge of the genesis of pulmonary tuberculosis as "a new era," with preventive and therapeutic possibilities transcending anything hitherto achieved in this field. Though the stethoscope will assuredly be used as long as man survives as a more or less intelligent being on the earth, it would seem that the time is passing when, in the hands of a distinguished and emphatic specialist, it proves, in the span of ten minutes or so, to be the sole arbiter of our fate.

SENSATION OF HEAT AND COLD.

THE study of the skin as a sense-organ has attracted less attention than the study of the other organs of special sense, and physiologists are not yet agreed on the nature and exact situation of the end-organs responding to thermal stimulation. Heat-therapy in its various forms is so frequently employed as an adjunct to treatment that any advance in the knowledge of the anatomical and physiological basis on which it must ultimately rest is welcome. In the current number of the *Journal of Physiology* is a report by H. C. Bazett, B. McGlone, and R. J. Brocklehurst on an investigation, carried out in the department of physiology at the University of Pennsylvania, on the temperatures in the tissues which accompany temperature sensations. By inserting thermo-couples into the skin at various depths, in the neighbourhood of warm and cold spots, the temperature changes were indicated by galvanometer deflection and recorded simultaneously with signalled temperature sensations. Small metal applicators, heated or cooled by circulating water, were placed over the selected areas of skin. Surface measurements showed that the temperature of the applicator was never reached by the skin, but was only slowly approximated. The rate of penetration of the thermal change was found to be 0.5 to 1.0 mm. per second, and was slowed by vascular dilatation. Warmth was found to be conducted more rapidly than cold. The latency of sensation was measured and correlated with the rate of penetration, allowance being made for the time taken in nervous processes. The estimated depth of the organs concerned was found to be 0.6 to 0.2 mm. for the end-organ for

¹ Meddelelser fra Vejlethjort Sanatorium, 1930, pp. 28.

warmth, and 0.15 to 0.1 mm. for that for cold, in the skin of the forearm. If the very superficial position of these structures should be confirmed by other investigators, it is interesting to note that they are in a zone to which actinic rays can penetrate, a fact which may point to a possible explanation for the physiological interaction of heat and short-wave stimulation of the skin. The rapid falling-off of the temperature changes in the deeper tissues is demonstrated very conclusively by the photographic records of the actual temperatures at the various depths. The fact that paradoxical results, indicating temperature changes opposite in sign to those anticipated, were recorded in some instances is a further proof of the difficulties encountered when attempts are made to raise the temperature of deep-lying tissues by superficial applications to the skin. Recent research work in this country has shown that when the skin is heated by radiant heat the rise of subcutaneous temperature is dependent on the wave-length employed.¹ By focusing the light of a carbon-arc lamp on the skin with a glass lens it was found possible to raise the subcutaneous temperature several degrees higher than by employing a source of dark heat. The latter produced more scorching and was not tolerated so well. The coördination of recent work on the warming of the deeper tissues of the body is important, not only from the clinical point of view, but also because it must prove a very important consideration in our estimation of the value of any method of heating our houses and possibly of cooking our food. As far as clinical methods are concerned the most efficient way of raising the temperature of the deep tissues, of a whole limb or of an organ, and so far the only reliable and accurate method, is the passage through these tissues of the diathermy current. The temperature can then be raised at will to the optimum desired and by passing the current in the direction of the longitudinal axis of the limb the whole column of blood is warmed. But when the diathermy current is applied with a view of raising the temperature of the body as a whole, it is frustrated by the compensatory heat-regulating mechanism of the body and the normal body temperature is regained shortly after the onset of treatment.

STOCK VACCINE IN BRONCHO-PNEUMONIA.

THERE are well-known difficulties in estimating the value of any particular line of treatment in such a disease as pneumonia, but it might be thought that any really efficacious method would reveal itself in reducing the mortality of broncho-pneumonia in young children. There is, however, wide disagreement as to the value of vaccines in this disorder. An interesting study has recently appeared in a special number of the *Journal de Médecine de Lyon*² devoted to diseases of children where Dr. Ch. Gardère and Dr. J. Savoye deal with their experiences in 72 unquestioned cases of broncho-pneumonia in children between birth and two years of age. The cases were rigorously selected in the sense that only those patients with the classical symptoms and signs were admitted to the series, and every effort was made to exclude cases of bronchitis or other mild complaint, only too often included in statistics of broncho-pneumonia. Lobar pneumonia was eliminated as far as possible by radiological examination; tuberculous broncho-pneumonia was excluded by post-mortem findings or the presence of a positive tuberculin reaction; throat swabs were taken whenever the appearance of the fauces was suspicious; and finally all cases admitted in the last stages of the disease—i.e., dying within 24 hours—were omitted from the series, as were examples of terminal broncho-pneumonia in marasmic infants. Of the 72 cases that remained 34 were treated systematically with a stock vaccine in daily and increasing doses

until the temperature came down to normal, while at the same time the classical measures for treating pneumonia were adopted. Among these the mortality was 58 per cent. The remaining 38 cases were treated with various other remedies such as anti-pneumococcal serum, protein shock (injections of milk), and autogenous vaccines. Among these the mortality was 75 per cent., showing a difference of 17 per cent. in favour of stock vaccine. The authors, however, are careful to point out that three or four deaths more or less in either of the groups would have completely altered the final result. But while the value of their vaccines remain uncertain there are several points of interest in their analysis of the results. For example, the greatest apparent benefit from the vaccine was found in the age-group 6-12 months, while it failed completely, as indeed did any form of treatment, to help the secondary forms of broncho-pneumonia following whooping-cough, measles, and chicken-pox. Autogenous vaccines prepared from organisms present in the nasopharynx during an attack proved less efficacious than stock vaccine containing the organisms habitually met with in broncho-pneumonic lesions. Antipneumococcal serum was not only disappointing but actually harmful. The care paid by Dr. Gardère and Dr. Savoye to the accuracy of their diagnosis and their appreciation of the difficulties of assessing the results are to be set against the smallness of the series. The evidence they adduce in favour of stock vaccine justifies a more extended trial under similar rigorous conditions.

NOISE IN HOSPITALS.

HOSPITAL patients often have to put up with a perpetual disturbance by small noises, and Dr. Harvey Agnew¹ points out that this nuisance is largely due to the echo and amplification of sounds right through the building. This is, he says, partly a result of modern fireproof construction with tile or concrete on a rigid framework of steel. In residential houses the reverberation which characterises an empty room or building is overcome by furnishing and by various surfacing materials which absorb the sound and so prevent it from being thrown from wall to wall. The coefficient of absorption of various substances has been established on the basis of comparison with an open window; the absorptive value of which is taken as one. Carpets have a coefficient effect of 0.15 to 0.3, and heavy rugs from 0.3 upwards. Tiles made of fibre, felt, or mineral products may have a coefficient of 0.45 to 0.74, but linoleum or varnished wood only of 0.03, concrete of 0.015, and terrazzo or marble 0.01. Ordinary smooth plaster ceilings are said to reflect a higher percentage of sound waves than a mirror does of light waves. The long, open tunnel corridor and lift shaft transmit sounds from end to end of the hospital. Much noise can be eliminated by breaking the corridor at frequent intervals with self-closing doors and enclosing the lift shaft and stair wells. Cross-beams across a corridor ceiling help to break sound waves, and ward doors set back from the corridor line stop conduction along the walls. Although terrazzo is a clean and durable flooring it is noisier than linoleum or rubber, and amplifies the sound of footsteps while linoleum deadens them. Better than ordinary concrete are cinder concrete or "aerocrete;" the latter is made with a specially prepared cement which breaks up the admixed water into gases and makes the concrete spongy and light. Few modern buildings show any serious attempt to make the walls sound-proof. A good filler for this purpose is powdered gypsum, which is also strongly fire-resisting. Dr. Agnew quotes Prof. Sabine as saying that a 2-inch air space has as much insulating power as a 4½-inch solid brick wall, provided the space is not bridged by anything rigid; but even a single nail driven right through will cause vibration on the inner surface.

¹ Hill, L.: *Journal of Actinotherapy*, March, 1929.
² Feb. 20th, p. 125.

¹ Canadian Med. Assoc. Jour., March, 1930, p. 414.

In a new building sound transmission along the ceiling can be reduced by suspending the ceiling from special hangers broken by felt pads. Old ceilings can be coated with a sound-absorbing material, such as an acoustical plaster made of pumice particles bound with cement or gypsum. The entry of street noises into wards can be reduced by reflectors outside the windows and baffle boards faced with sound-absorbing material fastened vertically 4 inches inside the window. Much annoyance may be caused to patients by loud buzzers or bells on the telephone system, the clicking of noisy locks, and the noises of plumbing. Knobs and clicking latches can be replaced by hooks, and doors can be provided with checks and springs. A new plumbing silencer has recently been perfected.

That elaborate precautions for the suppression of noise are no unnecessary fad has been shown, it is stated, by Laird's experiments at the Colgate Psychological Laboratory. He found that a passing truck, without wakening a sleeper, may so disturb him that his systolic blood pressure rises 20 mm., while increased muscular tension is recorded by a galvanometer. Obviously this response must have an exhausting effect upon the nervous system, and in a patient who is seriously ill may make possibly a difference between recovery and collapse.

THE SPREAD OF PUERPERAL SEPSIS.

THE earlier part of Dr. Macgregor's report¹ on puerperal infection in maternity hospitals describes a series of outbreaks which were all severe, rapid in spread, and extensive in incidence, considering the number of patients exposed to risk. In one group infection was introduced by the admission of a case of septic abortion; in a second group the origin of infection was uncertain, but cases recurred after the wards had been closed for some days and reopened with a new nursing staff; while in a third group the infection possibly came from a woman with persistent pyrexia ascribed to bronchitis; or, later, from a midwife with a septic finger. The report makes it clear at least that puerperal infection can spread readily under the average conditions obtaining in a nursing home, and that it tends to be persistent. On the other hand, cases of septic infection often occur in hospitals without giving rise to other cases, and this is no doubt because they are recognised early and strictly isolated before removal. No relationship was found between the presence of hæmolytic streptococci in the throats of the staff and the incidence of infections. Preventive measures, Dr. Macgregor points out, include the exclusion of parturient women who are infected, or presumably infected, from hospital wards. He quotes Dr. James Young's suggestion that cases untouched before admission should have their own institution, and that cases which have been subjected to certain kinds of interference before admission should be accommodated elsewhere. But cases where there has been manipulative interference do not necessarily become septic, and infection may occur after a single vaginal examination or after no interference at all. "It is doubtful," says Dr. Macgregor, "whether a water-tight administration based on segregation of patients in different institutions in accordance with the degree of interference before admission would be practicable or even a satisfactory method of meeting the difficulty." In the groups of cases investigated the infection appears to have spread with ease among patients whose confinements were otherwise normal, in spite of precautions and great alertness on the part of the staff. The transmission could therefore scarcely have been due to a temporary or accidental defect of technique. It is more likely, he thinks, that infection was propagated by hands, instruments, or dressings, than by infection of the staff and their conversion

into carriers of the organism. But it is reasonable to assume that infection may occur from a lesion on a nurse's finger or an organism carried in her throat. Apparently the passage of infection among parturient women is insufficiently hindered by the technique in vogue, and it must be decided whether the conduct of labour in institutions is susceptible of improvement to a point at which the danger is, at any rate, reduced to a minimum. The report suggests that the evolution of a "faultless technique" demands further attention.

LIMITATION OF NARCOTIC DRUGS.

THE report which the Advisory Committee on Traffic in Opium and Other Dangerous Drugs has recently submitted to the Council of the League of Nations shows that an important stage has been reached in its deliberations. The Committee has devised a plan for estimating the world's legitimate requirements of narcotic drugs, and a workmanlike scheme for approximating world production to these requirements and apportioning the amounts to be manufactured and supplied by the various producing countries. It is proposed that each country should furnish annually to a central authority an estimate of its requirements for medical and scientific purposes of the drugs in question, production to be limited to the total amount of these estimates. The calculations would be based on the actual legitimate consumption at the present time, but each country is to be allowed to budget for a margin of supplies to cover possible fluctuations, provided that the amount is stated separately. In addition, facilities are to be given for establishing reserve stocks, but it is proposed to endow the central authority with power to intervene in the event of estimates appearing to be excessive. A pooling arrangement is to be made by manufacturing countries to each of which will be apportioned the amount it will be eligible to contribute to the pool. If the scheme can be put into operation and worked successfully, the problem of controlling the narcotic drug traffic will be solved at its very source, and the domestic supervision of the traffic by each nationality will be greatly facilitated.

INCIDENCE OF TUBERCULOSIS AMONGST HOSPITAL NURSES.

In the March number of the *Canadian Medical Association Journal* Dr. E. L. Ross gives an account of 60 nurses who were admitted to the Manitoba Sanatorium suffering from tuberculosis. These nurses were in course of training or had finished their course at 20 different hospitals, but 54 of them came from institutions in Manitoba, so that the investigation applies almost entirely to this province. Of the 60 nurses who developed clinical tuberculosis, 50 of them broke down during their period of three years training or within one year of finishing it. Fifteen of them were below the age of 20 when this happened and 34 not yet 22. In a previous series of 69 breakdowns it was found that 81 per cent. of the nurses had begun their training before or at the age of 22. The figures suggest that the younger nurses are more likely to break down and that infection is apt to occur during or shortly after training in hospital. The incidence of tuberculosis amongst these nurses was about 6 per cent., a figure far above that for other women of their age-group; this agrees with the observations¹ made by Dr. J. Heimbeck in Oslo, where tuberculosis was much more rife amongst nurses than the general population. He found that it developed far more commonly in nurses who had a negative than in those who had a positive Pirquet reaction at the outset of their training. Of Dr. Ross's 60 cases, 34 had an acute onset which suggests a recent infection; in 19 of them the lesions were hilar or basal, and most of them did well with pneumothorax treatment. In this country, also,

¹ Puerperal Infection in Maternity Hospitals: A Report to the Department of Health for Scotland. By A. S. M. Macgregor, M.D., Medical Officer of Health for Glasgow. H.M. Stationery Office, 1930. Pp. 20. 9d.

¹ Arch. Int. Med., 1928, xli., 336.

it is familiar experience that acute tuberculosis developing in a young adult frequently affects the middle and lower portion of the lungs and, though apt to spread rapidly and end fatally, is none the less amenable to rest, and especially to pneumothorax treatment, in the early stages. The type and course of the disease do not seem to differ from that which occurs in other women of that age-period, but it seems unquestionable that nurses are especially liable to contract tuberculosis. We should be glad to know whether Dr. Heimbeck's observation that the tuberculin test is so frequently negative in those subsequently affected is true for other communities.

THE ŒSTRUS-PRODUCING HORMONE.

A GREAT deal of work on the ovarian hormones is being done both here and abroad, and in some ways their nature and significance has lately become much clearer. The problem is difficult because their recognition in fluids and organs depends on biological tests, which makes it impossible to be sure that all the Œstrus-producing extracts prepared from many tissues, including those of the male, are identical in constitution. In such circumstances the isolation of the active substance in a pure form, especially when crystalline, is of considerable importance. Even so, the elucidation of its chemical constitution may be difficult, and its artificial preparation still more difficult. The first report of the preparation of the hormone in crystalline form was made by E. A. Doisy at the Thirtieth International Physiological Congress in August of last year. This author has not yet published his full results, but in the preliminary statement then issued he said that the amount required to restore the sexual cycle in castrated female rats was one eight-millionth of a gramme of the crystalline material. Since this announcement several other workers have obtained crystalline products of similar activity. Last December A. Butenandt, using a preparation from the urine of pregnant women, succeeded in obtaining a sufficient amount of the crystalline material, to which he gave the name "prognynon," to study its chemical properties in some detail. This work has already been reviewed in these columns.¹ Details of the method of testing used have recently been published,² and the animal tests are described in full. Complete details of preparation have not yet appeared. The name suggested by Butenandt is open to objection, inasmuch as it was in use previously, and refers to a commercial (non-crystalline) product which was, in fact, the material furnishing the starting-point of Butenandt's research, and not its final result. Crystalline preparations have also been briefly described by Laqueur, Dingemans, and Kober,³ and more fully by H. Wieland, W. Straub, and Dorfmueller,⁴ and by Marrian.⁵ Butenandt considers that, on the basis of the animal standardisations, the products of the two former groups of workers are much cruder than his own preparation. It is well known that varying results are obtained according to the exact method used in carrying out the animal test, so that such criteria of purity need careful investigation and comparison before they can be accepted as conclusive. Butenandt, in his most recent publication mentioned above, now states that by giving a divided dose of his crystalline product spread over a period of 48 hours the activity is increased to the astonishing figure of 35 to 40 million mouse units per gramme of material.

A considerable contribution to this interesting subject is now made by Frattini and Maino in a paper on the preparation of the follicular hormone in a crystalline water-soluble form.⁶ The term "follicular

hormone" is used to indicate the supposed source of the hormone in the liquor folliculi of the Graafian follicles. Since this point is disputed, it seems better to use some other description, of which the terms "œstrus-producing hormone" or, as A. S. Parkes has suggested, "œstrin" appear to be the least confusing and clearly refer to the most marked action of these preparations—namely, the restoration of the œstral cycle in the ovariectomised female animal. These workers have found it possible to obtain, and in a crystalline form, an œstrus-producing hormone from the ovary and urine of pregnant women by a method for the extraction of this substance different from those employed by other workers. Further, they have been unable to obtain this crystalline body from the urine of non-pregnant women at any period of the menstrual cycle, or from the urine of males. The main features of their method are as follows:—Preliminary purification is obtained by treating concentrated urine or the filtrate obtained from macerated ovaries with neutral salts. From the precipitate the active hormone is extracted with alcohol. The impurities are removed by acids and alkalis, and by successive precipitation with salts of the heavy metals which are subsequently eliminated by sulphuration and extraction with ether. The crystals obtained after evaporation of the ether are needle-like in character, as illustrated in photomicrographs. They differ a little in size according to the source of origin. The physical and chemical properties are provisionally mentioned, but are to be described more fully in a subsequent paper. Sterols are suggested as a possible chemical constitution of the substance. Physiologically it appears to be somewhat less active than the preparations described above, the mouse unit by the divided dose method being given as one-millionth of a gramme. Whether these various crystalline substances are the same substances or whether they still consist, even after such exhaustive purification, of mixtures of the active substance with some crystalline "impurity" remains for the future to decide. At present full reports are lacking in most of the cases mentioned above, and it would be premature to compare these results until full details are available. The degree of purity already reached is such as to tax the most sensitive methods of chemical analysis and research, and this, combined with the exorbitant amount of material required as the starting-point, exerts a restraining influence on extensive chemical work on this substance. These difficulties are evidently being at present rapidly overcome, and the importance of this extremely potent preparation justifies the expenditure of so much energy and skill on the elucidation of the problem.

IMMUNISED SERUM IN POLIOMYELITIS.

ON various occasions we have referred to the treatment of poliomyelitis with serum administered at an early stage. The greatest difficulty in this mode of treatment is to recognise the disease early enough, but there is also another difficulty—namely, that the only efficacious serum available has been that of human beings who have suffered from poliomyelitis. Attempts to produce artificially a serum with antiviral properties have hitherto been unsuccessful, and the only animals whose blood has been shown to contain specific antibodies are monkeys which have actually had the infection. In a recent paper,¹ however, Dr. R. W. Fairbrother, who is working at the Lister Institute in London, describes the production and the testing of a serum with anti-poliomyelitic properties which has been obtained from the horse. The animal received, over a period of some two months, 15 graded injections of an emulsion prepared from the spinal cord of monkeys which had died of poliomyelitis. The strain of virus with which these monkeys had been infected was an especially powerful one, and it had been found

to give very consistent results. The disease which it produced had an incubation period of about five days, and death always followed three or four days after the onset of symptoms. The minimal infective dose was found to be between 0.0005 and 0.003 c.cm. of emulsion. The injection of emulsified spinal cord material from these monkeys produced in the horse no definite sign of reaction as determined by pulse and temperature. Blood was withdrawn before beginning the inoculation and at intervals during the latter part of the series, and the serum was submitted to severe tests to determine its protective properties. The method of testing consisted in mixing small portions of serum with an amount of infective emulsion equivalent to at least 100 times the minimal infective dose, and injecting the mixture intracerebrally into monkeys. Control animals received similar injections of virus emulsion mixed with saline. It was found that the normal serum of the horse taken before inoculation had no effect on the virus, the incubation period in the monkey subsequently infected being within the usual limits. The serum taken from the horse towards the end of the course of inoculations showed definite antiviral properties and, provided the amount of serum was equal in quantity to the amount of infective emulsion employed, no poliomyelitis resulted in the monkeys from injection of the mixture. The power of the horse's serum to neutralise the virus was found to increase *pari passu* with the strength of the inoculation which the horse had received, the serum of the third bleeding having a distinctly stronger action than that obtained at the first bleeding. After a resting phase of two months, more blood was taken from the horse and was tested in a similar way. The results of this test were deprived of their full significance by an intestinal infection in some of the monkeys, but it appeared that during the resting phase the antibodies in the serum had decreased. An attempt was later made to assess the curative action of this serum by injecting it into monkeys at various intervals after they had been infected with the powerful strain of poliomyelitic virus which was being used. Unfortunately, however, these experiments were vitiated by the occurrence of another infection in the experimental animals. Some comparative tests have also been made with human convalescent serum, and from the results obtained it appears that the antiviral content of the serum obtained from the horse at the end of the course of inoculations was at least as great as that of the human convalescent serum. Since the diagnosis of poliomyelitis in the earliest stages is as yet impossible, the production of serum from animals may not have an immediate practical application, but if serotherapy is to be useful during epidemics it is apparent that the serum must be available in large quantities in order that it may be given even to doubtful cases and possibly to certain contacts. For this reason Dr. Fairbrother's work may well prove of great practical importance.

At its session on March 28th Dr. Arnold Netter² told the Société Médicale des Hôpitaux de Paris about a case which he described as "rapid cure, following injections of immunised monkey serum, of poliomyelitis in the preparalytic stage." The patient, a child of five, received, in the course of four days, 40 c.cm. of serum from an immunised hamadryad monkey and also 50 c.cm. of antipoliomyelitic horse serum. Recovery was complete.

THE ENGLISH CONJOINT QUALIFICATION: ADMISSION OF FOREIGN GRADUATES.

THE new edition of the regulations for the diplomas of L.R.C.P. and M.R.C.S. contains important alterations which will take effect after July.

Candidates for the licence are required to complete five years of professional study. Before beginning this they must pass a recognised examination in general education and also

an examination in chemistry and physics equivalent to Part I. of the "pre-medical examination" in chemistry, physics, and biology. The professional examinations are two in number, and each has two sections, as follows:—

First Professional Examination.—Sect. I. Anatomy and Physiology. Sect. II. Pharmacology and Materia Medica.

Final Professional Examination.—Sect. I. Pathology. Sect. II. Medicine, Surgery, and Midwifery.

The most important alteration is in the conditions under which students and graduates from abroad are admitted to the Final Examination. The new regulations may be summarised as follows:—

1. A candidate holding a licence in India, whether he has completed four or five years' curriculum—is required: (a) to pass a recognised Preliminary Examination in General Education, in accordance with the Regulations of the Examining Board in England; (b) to pass the First Examination in Anatomy, Physiology, Pharmacology, and Materia Medica; (c) to complete two years' (24 months) Medical and Surgical Hospital Practice in a recognised Medical School and Hospital in this country after passing Sect. I. of the First Professional Examination. Admission to one subject of the Final Examination is allowed after 18 months of such Hospital Practice.

2. A candidate who has qualified in India after a full curriculum of not less than five years at certain recognised Medical Colleges is exempted from Sect. II. of the First Examination and requires only one year's Hospital Practice before admission to the Final Examination.

3. Candidates who have not obtained a licence or other qualification in India, are required to pass the Preliminary Examination and the Pre-Medical Examination, to complete the full curriculum and to pass the First and Final Examinations.

4. Candidates who have completed part of the curriculum at a recognised Medical College, but have not qualified in India, are required to pass a recognised Preliminary Examination in General Education, but are exempted from the Pre-Medical Examination, and are allowed to count such part of the curriculum thus completed in India. They must pass the First Examination and complete the full curriculum before admission to the Final Examination.

5. Candidates holding the Diploma of the National Board of Medical Examiners of the United States of America are admissible to the Examinations for the L.R.C.P., M.R.C.S., under the same conditions as Members of recognised Universities in the British Possessions.

6. Members of recognised Universities outside the British Possessions are admissible to the Examinations under the following conditions: (a) Graduates in Medicine and Surgery are required to pass the First Examination, and subsequently to complete 12 months' Hospital Practice at a recognised Medical School and Hospital in this country, before admission to any part of the Final Examination; (b) Undergraduates are required to complete the full curriculum of 33 months for the Final Examination at a recognised Medical School and Hospital in this country, after passing the First Examination. Hitherto it has been possible for foreign graduates to proceed at once to the Final Examination.

Prof. J. J. R. Macleod, F.R.S., will deliver the Oliver Sharpey Lectures at the Royal College of Physicians of London on Tuesday, April 29th, and Thursday, May 1st, at 5 p.m. His subject will be *Diabetes as a Physiological Problem*.

ROYAL INSTITUTE OF PUBLIC HEALTH.—The preliminary programme of the next annual congress of this institute, which will be held at Portsmouth from June 4th to 9th, has been issued. Among the discussions which will take place in the various sections is one on National Health and the Local Government Act of 1929, and one on Radium and Cancer Clinics (Section of State Medicine and Municipal Hygiene). Papers read to the Naval, Military, and Air Section will include those on Post-Encephalic Parkinsonism and Military Pensions and on the Control of Malaria at H.M. Naval Base, Singapore. The Section of Industrial Hygiene will discuss Health in Seafaring Occupations, the Health of Women and Girls in Industry, and the Health of Dockyard Workers among other subjects. The Prevention of Sickness and Death in Motherhood is the main subject for debate at the Section of Women and Children and the Public Health, while papers will be read on the cognate subjects of Post-Puerperal Disabilities in Women and the Hygiene of the Domiciliary Labour Room. In the Section of Tuberculosis the Present Position of Surgical Treatment of Pulmonary Tuberculosis will be discussed.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

LXVIII.

SIGNIFICANCE OF PROTOZOA, SPIROCHETES, AND HELMINTHS IN THE BLOOD.

PART I.*

IN no other branch of medicine does laboratory diagnosis assume more vital importance than in the diseases of tropical origin; so that in order to estimate the import of a positive blood examination, and so as not to underestimate the significance of a negative finding, it is essential that the practitioner should be familiar with the life story of organisms found in the blood in tropical disease. In other words, in almost all blood infections the investigator is playing a game of hide-and-seek with minute parasites which are influenced by a number of incompletely understood circumstances. Therefore, one negative result, or even a series of negative results, need not necessarily invalidate a diagnosis which is rendered probable on clinical grounds.

The Malarial Parasite

In tropical practice malaria assumes the chief place, and at the outset it is necessary to bear in mind that this term embraces not one disease, but a group of fevers due to three distinct parasites. The life cycle of the *benign tertian* and the *quartan* in the blood stream differs very considerably from the *malignant* or *subtertian*. In the two former the process of schizogony takes place in the red blood corpuscles circulating in the peripheral blood, while in the latter the greater part of this process is evolved within the capillaries of the internal organs. It is necessary to recapitulate a few well-ascertained facts concerning these parasites and their associated diseases.

The *benign tertian* is the most widely spread form of malarial infection. The parasite is apparently common in the true tropics, subtropics, and even in temperate countries such as Russia and Holland, but appears to be absent or extremely rare in tropical and West Africa. It is the form which is most abundant in the blood stream during the febrile paroxysms and, unless it persists unchecked and the bodily resistance is low, no grave anaemia may ensue, though it may be difficult definitely to diagnose this form of malaria in the quiescent or afebrile periods. Relapses of benign tertian malaria may ensue at long intervals after the initial attack. It is comparatively common for the first relapse to take place one year after the first paroxysm; and in the interval the patient may show no outward evidence of infection at all. The parasite appears to have a life span of considerable length in the human body and to be viable (or liable to recur in appreciable and easily recognisable numbers) for three years from the initial infection. It is improbable that it can persist for a longer period, a fact which is not adequately recognised—too often this non-appreciation is the cause of errors in diagnosing (on clinical grounds) recurrent malaria in an individual who has left a malarious district for ten years or even longer. During the actual rigor the parasites can be found in the greatest numbers in the ring stage, at a later period as more mature schizonts. It is a common error to suppose that it is fruitless to examine the blood during the apyretic periods, or immediately after the deferrescence of the fever. I regard it as essential that a

prolonged blood examination should be done by an experienced microscopist in every case of suspected malaria, for often, in the absence of any other suggestive circumstance (such as anaemia and splenomegaly) scanty parasites in the gametocyte stage may be found, and the definite recognition of one such organism will definitely clinch the diagnosis. The benign tertian parasite is readily affected by quinine in so far as the number of circulating parasites rapidly become distorted and disappear, but the gametocyte stage is the least susceptible and often persists after quinine therapy has been instituted for some considerable time. In contradistinction to the other two forms, periodic relapses with large numbers of parasites in the blood are liable to recur in spite of prolonged and full therapeutic dosage with quinine. It can be taken as proven that in every benign tertian paroxysm parasites can be demonstrated in the blood with ease—but some weeks afterwards diagnosis by this means may be impossible, so that finer changes in the red blood cells, basophilic stippling, polychromasia, and the proportional increase of the large mononuclear cells (mononucleosis), have to be relied upon to suggest a probable diagnosis.

Quartan malaria has by no means such a wide distribution as has benign tertian. Wherever it occurs in the tropics it has a patchy local distribution and it is found sparingly in more temperate climates, such as Macedonia, Bulgaria, and Italy. It most commonly occurs in children in whom it may cause singularly little disturbance, and it may not produce any obvious outward form of disease. Apparently, this parasite is most easily tolerated by man, and, as a rule, produces less dramatic attacks of fever than does the benign tertian. The parasite may be easily recognised in its more advanced stages by its peculiar morphology. It persists in appreciable numbers in the blood during the apyrexial period and may sometimes be found when the patient is apparently in good health. Its other characteristics are its longevity in the blood stream—as far as is known this greatly exceeds the other two species—so that a single infection may persist and produce relapses for as long a period as seven years. For these reasons quartan infection in the blood can be more easily detected than in benign tertian. Its parasites are less easily destroyed by quinine than are those of the other two species, so it comes about that unaltered forms may be demonstrated in the blood stream for ten days or more, subsequent to its administration.

In the *malignant* or *subtertian* infection a much more complicated problem presents itself. As has been already stated, the parasite reproduces itself by sporulation in the capillaries of the internal organs, such as the spleen, liver, pancreas, heart, and brain. The blood-supply of these vital parts may be seriously interfered with or even temporarily blocked. A proper understanding of these facts will assist the practitioner in recognising the protean clinical manifestations of subtertian infections and at the same time will enable him to appreciate some of the difficulties in microscopic diagnosis. Examination of the peripheral blood in subtertian malaria is often negative. This may happen when in fact large numbers of parasites are proliferating in the internal organs of the body. The intermediary stages of schizogony do not normally occur in the peripheral blood, so that the youngest or ring form, and the fully developed crescent or gametocyte stage, are the only ones which are normally to be found circulating in the blood in subtertian infections. I am convinced that in early cases of subtertian malaria the parasite in the ring stage may be found in the blood stream without being associated with any external signs of illness. The onset of what may eventually prove to be a very serious or sometimes fatal illness is so insidious that as a matter of routine I find it advisable to examine the blood of every one returning from the West Coast of Africa, whether or no they present a history of previous febrile attacks. On the other hand, during an acute attack,

* Part II. will appear next week.

such as the well-known bilious remittent form, the parasites may exist in enormous numbers and multiple infections of red blood corpuscles may be found. The gametocyte, or crescent stage, is rarely seen in fresh infections in Europeans in the tropics. It appears usually in longstanding cases where anæmia and cachexia are very evident, or in patients who have returned to temperate climates after suffering severely from subtertian fever. In fact, the circumstances underlying the appearance of this parasite in the peripheral blood are so variable that it is difficult to describe them concisely. Subtertian malaria may provoke the most serious or even fatal symptoms, and yet the parasite may not be demonstrable in the peripheral blood. This is often true in cerebral malaria with coma, in what is known as the pre-blackwater fever state, and even in an average severe case of subtertian fever. I have seen cases with multiple rigors, bilious vomiting, and splenomegaly in whom repeated and prolonged search of the blood has failed to reveal a single parasite. In order to facilitate microscopic diagnosis in this important fever, the thick drop method is frequently employed, though with the possible exception of crescents, which may be more easily demonstrated, its utility to the clinician is questionable. There are other distinctive characters of subtertian malaria. It has the shortest life-span in the human body, and a patient leaving the endemic area need not fear relapses after a residence of nine months to a year in a temperate climate. During the whole of this period, however, the liability to the development of pernicious symptoms and to blackwater fever may persist when he is exposed to over-fatigue or to cold. Subtertian infections are susceptible to the action of quinine, and the less mature stages, such as the rings, rapidly disappear from the blood stream under its influence. The crescent, or gametocyte, is least affected by therapeutic doses, but appears to be more readily destroyed by plasmoquine. When the anæmia is advanced—and it may approach the pernicious type in malaria cachexia—I have found that the ring forms and the crescents are particularly difficult to demonstrate, and it is these cases which should be regarded as most serious from the point of view of prognosis and liability to the development of blackwater fever. From the foregoing it will be understood that a diagnosis of subtertian malaria has sometimes to be made in the absence of a positive laboratory finding. Subtertian infections are more usually associated with definite splenomegaly, secondary blood changes, and a leucopenia than are the other two forms.

Double or Multiple Infections.—Malaria may complicate any other form of disease, especially enteric and dysentery infections, and it may even complicate itself. In the tropics it is comparatively common to find double infections of *benign tertian* and *subtertian* and such an occurrence necessarily influences treatment and prognosis. Serious or alarming symptoms arising in a case of supposedly simple benign tertian fever can very often be ascribed to a coexisting infection with the latter parasite, and this is usually the case in which blackwater fever supervenes consequent upon a paroxysm of benign tertian. Very rarely all three species of parasites are found in the same individual.

PHILIP MANSON-BAHR, D.S.O., M.D., F.R.C.P.,
Physician to the Hospital for Tropical Diseases, London;
Consultant to the Colonial Office and Crown
Agents for the Colonies.

HOSPITAL COSTS.—Last year each of the 1164 in-patients at Leeds Hospital for Women stayed an average of 13.6 days, and cost £0 17s. 5½d.; out-patients cost about 2s. each. At York County Hospital (2505 in-patients), the cost was £8 9s. 7d., a reduction of 14s. 10d., and the average stay 24 days, a reduction of one day. On the other hand, at the Feilding Palmer Cottage Hospital, Lutterworth, (89 in-patients in 16 days), the expenditure per head, at £0 15s. 8d., was an increase of £1 7s. 6d. on the preceding year. At Rugeley District Hospital, 185 in-patients (17.7 days' stay) cost £2 6s. 5d. per head per week.

Special Articles.

THE EFFECT OF ULTRA-VIOLET LIGHT TREATMENT ON YOUNG CHILDREN.

BY ETHEL CASSIE, M.D. EDIN., D.P.H.,

ASSISTANT MEDICAL OFFICER OF HEALTH (FOR MATERNITY AND
CHILD WELFARE), BIRMINGHAM;
AND

URSULA COX, M.R.C.S. ENG., D.P.H.,

ASSISTANT MEDICAL OFFICER FOR CHILD WELFARE, BIRMINGHAM.

RECENT observations on the therapeutic use of ultra-violet light have made the doubters more doubtful, but have failed to lessen the enthusiasm of the advocates. What chiefly emerges is the insufficiency of objective data. Those actually using the ultra-violet lamps and watching the effects on their patients are almost always convinced that rapid beneficial results are obtained, but these impressions are of little value except as personal convictions. The difficulties of obtaining objective data were evident in the investigation which we are about to describe, but certain definite facts undoubtedly emerge.

We have been closely concerned in the supervision of the Birmingham Child Welfare Light Clinics, of which there are now nine in the city. These clinics treat children under five years of age, mainly for rickets and debility, and during 1928 no fewer than 1375 children attended the clinics, making 16,481 attendances. This seemed to offer a large field for investigation, but careful inspection of the records showed that only 346 were sufficiently complete for detailed study. In a large number attendance at the clinics had been interrupted by illness in the house; in others the final medical examination had been omitted because the mother failed to attend with the child. It will be understood that prolonged regular attendance is often difficult to obtain.

The procedure for admission to the light clinics is as follows. Children are recommended by the doctors at the child welfare centres and by family practitioners. They are then called to the medical examination clinic, where they receive a complete physical examination and, if considered suitable, light treatment is prescribed. In some cases other suggestions are made and no light treatment is ordered. The dose normally given is a fourth of the erythema dose (calculated on an average adult), and this is checked by giving an erythema test to each child, any undue sensitiveness indicating a reduction of the dose. Treatment is given twice weekly, and the dose is not progressively increased, since the mercury-vapour lamp is used, and there is no pigmentation. The lamps are all of the Kelvin Bottomley and Baird pattern, either 220 or 440 volts. The child attends for six, eight, or twelve treatments, and is then seen again by the medical officer.

The 346 records were selected for the following reasons:—

- (a) Regular attendance at the clinic.
- (b) A weight record at the beginning and end of treatment.
- (c) No intercurrent event which made the evaluation of the result difficult—e.g., intercurrent illness, hospital treatment, country holiday.

The conditions from which the children were suffering can be classified broadly in the groups shown in Table I., and defined as given below.

1. **General Debility.**—This group comprises children of poor physique, unusually underweight and not gaining, frequently flabby and anæmic, and of subnormal vitality. The condition frequently follows an acute illness or infection. It does not include children suffering from any definite catarrhal condition; these are all included in the next group

2. *Catarrhal Cases.*—This group includes those children suffering from or excessively liable to catarrhal infections, such as rhinitis, tonsillitis, bronchitis, and otorrhoea. The majority suffer also from general debility.

3. *Rickets.*—Only those cases are included in this group where rickets is shown by X ray of the wrist bones.

4. *Malnutrition.*—This group includes those cases not suffering either from catarrhs or general debility but who, from one cause or other—e.g., inadequate diet, insufficient rest—are considerably below the normal weight and are failing to gain. Often no definite cause for the condition was assignable.

5. *Debility Due to Mismanagement.*—This group includes those children who may be summed up as "the spoilt child," and whose physical health has suffered.

6. *Amyotonia.*—This group includes children who have nothing much wrong with them but who are lethargic and flabby. Frequently they are overweight.

7. *Nervous Excitability.*—This group includes nervous children who are over active and excitable, thin, not gaining weight, and frequently suffering from sleeplessness, night terrors, and anorexia.

TABLE I.—Classification.

Conditions.	Age-groups.				
	(1) 12 wk. to 1 yr.	(2) 1-2 yr.	(3) 2-3 yr.	(4) 3-4 yr.	(5) 4-5 yr.
General debility ..	31	67	14	6	12
Catarrhal cases ..	22	34	19	10	8
Malnutrition ..	9	7	2	3	—
Rickets ..	4	20	6	1	—
Debility due to mis- management ..	2	12	6	3	—
Amyotonia ..	2	10	2	—	1
Nervous excitability ..	3	6	3	1	1
Other conditions* ..	5	4	3	3	4
Total ..	78	160	55	27	26

Total=346.

* Other conditions include bronchitis, asthma, and skin conditions.

It will be seen that the conditions treated were various, but the composite picture is that of a child failing to gain in weight, and a cause of anxiety to the parents from the obvious evidence of failure in normal health. These children had almost all attended child welfare centres and the usual advice about diet and hygiene had been given.

Weight.

The simplest objective data of progress lay in the observation of the weight record of the child during treatment. The cases were placed in age-groups, and the average gain in weight ascertained as compared with the average for the normal child. The result is recorded in Table II.

TABLE II.—Effect on Weight.

Age-group.	No.	Average period of treat- ment in weeks.	Average gain in weight per week in ounces.	Percentage gain as compared with normal child.	Average gain in weight of normal child per week in ounces.
1. (under 1 yr.)	78	11	4.1	113.8	3.6
2. (1-2 yrs.)	160	12	2.1	123.5	1.7
3. (2-3 ..)	55	11	1.0	125.7	1.4
4. (3-4 ..)	27	12½	2.2	157.1	1.4

This shows a higher average gain in each age-group than is made by the normal child, and this in a group of children who were all more or less unhealthy and had failed to gain weight for some time. Further analysis was obviously required, however, and Table III. was prepared, showing the actual numbers gaining above, below, and at the average rate in each age-group, and also showing the type of home from which the children came, in case this factor should influence the result. It will be noted that the larger proportion came from good homes. This is due to the selection of those

cases making a regular attendance. The Table shows clearly that the type of home did not affect the result in any definite way. In passing, it should be noted that no free food or cod-liver oil is allowed in any of these cases by the clinics.

Table III. shows a more marked effect from light treatment on the weight of children between one and four years of age. This is possibly associated with the fact that the city child is out-of-doors less at this period than before or after—i.e., the period following the perambulator stage and preceding the independent stage. Taking all the groups, 54 per cent. of the children gained above the average, 24 per cent. below the average, and 21 per cent. at the average. None lost weight, and this the authors believe should be attributed to the cautious dosage used. Any excess of ultra-violet light appears invariably to cause a loss of weight.

TABLE III.

Age-group.	Type of home.	Gain above average.	Gain below average.	Gain at average.	Total.

	Total ..	12 (46%)	14 (54%)	—	—
Total	..	190 (54%)	82 (24%)	74 (21%)	—
Total types of home.	Good 153 (44%)	Fair 73 (21%)	Poor 52 (15%)	Very poor 68 (20%)	—

Classification of Types of Homes.—"Good" implies the respectable artisan or middle-class household, where diet and hygienic conditions are reasonably good. "Fair" implies the artisan home where the diet is adequate but hygienic conditions not very good, probably from causes over which the parents have no control. "Poor" implies the home where the income is inadequate and diet and hygiene both very defective. "Very poor" means the home below the poverty line where the diet is most inadequate, in quality if not in quantity, and the hygiene very bad.

General Health.

In 271 cases the records were sufficiently complete to make it possible to estimate the degree of improvement obtained in general health. In order to eliminate any criticism, the greatest care was exercised in the classification, and if any doubt existed the case was not placed in the "improved" class. The totals show surprisingly good results, considering the severity of the classification. A very high proportion (83 per cent.) improved, and no less than 37 per cent. showed marked improvement and 6 per cent. striking improvement. In each individual group there was a definite improvement in over 80 per cent. of the cases, except in the mismanaged group, where it is a question

of affecting the mother rather than the child. The catarrhal cases included some with enlarged tonsils and adenoids awaiting operation (the delay usually amounts to three months after the child is placed on the waiting-list), and the improvement in health obtained by light treatment in this period is of definite value, though it would be preferable to avoid the delay in most cases.

The malnutrition cases received a certain amount of advice in addition to light treatment but these, as well as the majority of other cases, had already been under the care of the child welfare centres for some time and were sent as failing to improve.

The rickets cases are classified not in relation to rickets, but in relation to general health. The rickets, of course, healed in every case, but in very poor homes the general health does not improve concurrently, and it will be seen that in two cases there was no

TABLE IV.

Condition.	Cases.	Total Improving.	Improvement.	Improvement—		
				Marked.	Striking.	None.
Gen. debility..	86	76 (88%)	29 (31%)	39 (45%)	8 (9%)	10 (12%)
Catarrhal cases	75	61 (81%)	32 (43%)	25 (33%)	5 (5%)	14 (18%)
Malnutrition ..	20	17 (85%)	10 (50%)	7 (35%)	—	3 (15%)
Rickets ..	32	30 (93%)	12 (37%)	14 (41%)	4 (12%)	2 (6%)
Debility due to mismanagement	24	13 (54%)	10 (42%)	3 (12%)	—	11 (46%)
Amyotonia ..	14	14 (100%)	8 (57%)	4 (29%)	2 (14%)	—
Nervous excitability	11	9 (82%)	5 (18%)	7 (64%)	—	2 (18%)
Total ..	262	220 (83%)	103 (39%)	99 (37%)	18 (6%)	42 (16%)

improvement. The total number of rickets cases treated during the year was 293, and the small number included here is due to the incomplete records in this group. However, the results obtained are better than with cod-liver oil in home treatment; as a rule, the mothers bring their children for treatment but will not trouble to come for the final medical examination. With cod-liver oil the rapid improvement of nervous symptoms is not obtained and the mothers do not persevere with the treatment.

TABLE V.—Effects on Particular Symptoms.

Symptom.	Cases.	Total Improving.	Improvement.	Improvement—		
				Marked.	Striking.	None.
Appetite ..	120	93 (78%)	49 (41%)	38 (32%)	6 (5%)	27 (22%)
Sleep ..	77	59 (77%)	22 (29%)	25 (38%)	8 (10%)	18 (23%)
Nervous condition ..	76	50 (66%)	22 (29%)	20 (26%)	8 (11%)	26 (34%)
Flabby muscles	71	58 (82%)	31 (44%)	26 (37%)	1 (1%)	13 (18%)
Total ..	344	260	124	133	23	184

Four symptoms were studied: anorexia, sleeplessness, nervous excitability (fretfulness, bad temper), and lack of muscle tone. The result obtained was usually good, though 18 per cent. to 34 per cent. of cases in which there was failure to obtain improvement are noted. It must, however, be remembered that the mismanaged group is included, and without change of environment these are little affected.

Conclusion.

Careful observation of the effects of light treatment on city children gives definitely encouraging results. The curative effects of ultra-violet light on rickets is an established fact. Whether it is of real value in other directions remains to be proved. On young children, at the period of life where light deprivation is most common in cities, it appears to act as a definite stimulant to metabolism. The effect on nervous symptoms is particularly interesting and very well marked. Is it possible to suppose that a more effective elimination of fatigue toxins is secured?

The well-marked effect on weight is striking. The height records were not sufficiently accurate to quote, but it is probable that the increase in weight is associated with increased growth.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 5TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 457 (last week 449); scarlet fever, 2426; diphtheria, 1464; enteric fever, 54; pneumonia, 1536; puerperal fever, 46; puerperal pyrexia, 102; cerebro-spinal fever, 22; acute poliomyelitis, 1; acute polio-encephalitis, 5; encephalitis lethargica, 14; dysentery, 9; ophthalmia neonatorum, 118. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on April 8th-9th was as follows:—Small-pox, 582 under treatment, 23 under observation (last week 570 and 28 respectively); scarlet fever, 2114; diphtheria, 2754; enteric fever, 21; measles, 1057; whooping-cough, 70; puerperal fever, 30 (plus 18 babies); encephalitis lethargica, 121; poliomyelitis, 2; "other diseases," 22. At St. Margaret's Hospital there were 15 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns including London there was 1 death from small-pox, 3 (0) from enteric fever, 134 (69) from measles, 9 (1) from scarlet fever, 30 (4) from whooping-cough, 51 (6) from diphtheria, 45 (15) from diarrhoea and enteritis under two years, and 61 (13) from influenza. The figures in parentheses are those for London itself.

The death provisionally classified to small-pox was assigned to Stepney (Met. Boro.). The deaths from enteric fever were reported from Dudley, Southport, and Hull. Fatal cases of measles were again widely distributed, with larger numbers at Manchester, 6; West Ham and Chester, each 4. Whooping-cough claimed 4 victims at Birmingham; diphtheria 9 at Liverpool. Diarrhoea accounted for 5 deaths at Birmingham and 4 at Liverpool. Birmingham and Swansea each reported 4 deaths from influenza.

The number of stillbirths notified during the week was 275 (corresponding to a rate of 41 per 1000 births), including 53 in London.

POST-GRADUATE MEDICAL EDUCATION.

THE committee appointed by the Ministry of Health in July, 1925, to draw up a practicable scheme of post-graduate medical education in London have now presented their report.¹ They begin by sketching the history of the subject and the present urgency of the problem. The lack of adequate provision for instruction in public health and for research in preventive medicine was remedied in 1922 by the establishment of the London School of Hygiene and Tropical Medicine, which was made possible by a gift from the Rockefeller Foundation. A defect that still remains is the absence of any hospital and medical school exclusively devoted to providing practical courses for doctors who wish to refresh their knowledge, learn about new developments, or participate in the clinical practice of a hospital. The committee urge the imperial, international, and national value of a British Post-graduate Medical School and its special value to the country doctor. They set themselves to establish, in the words of their terms of reference, "a practicable scheme" and have therefore not attempted to recommend anything too ideal to be translated into practical effect within a reasonable time. The scheme, they felt, must include a hospital, already large and capable of expansion, with the regular and ready provision of a substantial and increasing sum for its maintenance. It must also include the provision and maintenance of a medical school with staff, equipment, and premises at no point inferior to the best obtainable.

Schemes Considered but not Recommended.

The committee considered first the building and maintenance of a new institution. This would have

had the obvious advantages that site, design, and equipment could have been chosen in the light of most modern advice and that ample room could be provided for expansion. The committee soon realised, however, that this could not be called a practicable scheme, as its cost would delay its completion, at least for a considerable time. The committee felt it essential to have at least 400 beds available very soon after the inauguration of the scheme. They reckoned that the cost of the construction of the new building could not be estimated at less than £500,000, while the cost of maintenance would be not less than £100,000.

Secondly, the committee considered turning some existing hospital and medical school into the post-graduate centre. This would have preserved the traditions and reputation of an existing school, would have enlisted the help of a medical staff of high calibre and an enthusiastic group of lay supporters, would have ensured a building conveniently located and already serving a large area, and would not have involved the expenditure of large sums on bricks and mortar. The committee felt quite definitely, however, that undergraduate teaching must cease in the selected hospital and school, and they found that no suitable hospital was willing to accept this condition.

Thirdly, there was the possibility of using one of the existing voluntary hospitals without medical schools. The West London Hospital at Hammersmith was considered with especial care, as post-graduate medical education has been provided there since 1892. When the board of management of the hospital were informed that the committee desired the post-graduate institution to have 400 beds and that the board were to be held responsible for their maintenance, they viewed their financial responsibility very gravely but accepted it in principle. Detailed discussions proceeded, and it was estimated that about £350,000 would be needed to convert the hospital into a post-graduate centre and another

¹ Report of the Post-Graduate Medical Education Committee. H.M. Stationery Office, 1930. Pp. 37, 3d.

THE PROPOSED POST-GRADUATE MEDICAL CENTRE FOR LONDON.

A bird's-eye view of the Hammersmith Infirmary and Workhouse as it was planned in 1905 by the architects, Messrs. Giles, Gough, and Trollope (28, Craven-street, London, W.C.2), but which was not fully carried out from reasons of economy. The illustration is, however, of interest as indicating the lines on which the buildings lend themselves to completion. The actual lay-out may be seen on the map overpage reproduced from Stanford's Atlas of London. The northern block of buildings is the workhouse, now called the Hammersmith Institution, and the southern block is the infirmary, now called the Hammersmith Hospital. All the buildings were requisitioned as a hospital during the late war, and remained in use as the Special Surgical Hospital of the Ministry of Pensions from 1918 to 1924. The whole of the institution is under medical direction, Dr. J. Jenkins being superintendent of the hospital and assistant master of the institution.

£50,000 to equip the hospital and school. The cost of maintenance would probably prove to be about £100,000 per annum. The financial difficulties before the Board were therefore serious, but the scheme was apparently the only practicable one. While everybody concerned was hesitating, the committee found themselves faced early in 1929 with another possibility, involved in the proposed Local Government Act. They realised that when the Act became law nearly thirty public hospitals would be transferred to the London County Council, and the possibility of using one of these public hospitals for their post-graduate scheme could not be ignored.

The Scheme Recommended.

After considering the public hospitals available and excluding the unsuitable ones, the committee reduced the possibilities to six and then to two, and finally selected the Hammersmith Hospital, which is situated in Ducane-road, Shepherd's Bush, on a site of 14 acres. It was built in 1905 and has 400 beds, of which 334 are at present medical and surgical, 15 gynaecological and obstetric, and 50 paediatric. There is a resident medical superintendent and four assistant officers, with a consulting staff of six surgeons, two ophthalmologists, two physicians, two dermatologists, two bacteriologists, a dentist, and a radiographer. There is thus ready to hand a relatively modern building which is exceptionally well laid out for its purpose and has the requisite number of beds. The committee feel that this gives them an asset equivalent in value to a large part of the capital sum which would otherwise have to be found. They cannot submit an accurate estimate, but they do not think that it ought to cost more than £250,000 to convert the Hammersmith Hospital into a post-graduate institution, to equip it, and to provide residential accommodation, partly there and partly at a hostel elsewhere. The committee are unable to see any reason why the maintenance of the hospital should not remain, as it would do otherwise, a charge on the ratepayers of London. The hospital will continue to be a public hospital for the sick poor of the city, and the committee do not feel that its association with the British Post-graduate Medical School will lay any increased charge upon the ratepayers. If there should be any increased charge it will be more than made up for by the restoration of patients to earning capacity and the development of medical knowledge.

Although the committee regarded their financial problem very seriously they have by no means sacrificed the medical and administrative points of view. The Hammersmith Hospital serves a large area on the west side of London with a population which is already dense and is still increasing, and does not share with the West London Hospital the disadvantage of admitting a very high proportion

of surgical casualties. The clinical material provided should therefore be just what is required. Since the London County Council has only just come into possession of the hospital it is obvious that a detailed scheme for a system of government has not yet been discussed. The committee, however, thought it better to submit their general scheme for acceptance before entering into the difficulties of administration. Another advantage of this hospital is the space around it, which leaves ample room for building a medical school and for any expansion which may be necessary. The West London Hospital has only two and a half acres of land.

The Hostel and Special Departments.

The committee think it best to build a hostel at some central spot within easy reach of the London School of Hygiene and Tropical Medicine, the other London hospitals, and the centres of recreation and social amenities. They hope to find a place which can easily be reached by road and rail from the Hammersmith Hospital. The Central London Railway, which serves Hammersmith, will be particularly convenient for students, as it also passes close to hospitals where special courses are likely to be provided and to institutions like the Royal Society of Medicine where students will look for medical literature and other aids to study.

Although special courses can be provided at special hospitals the committee considers that the centre itself will not be complete unless it includes departments for the study of tuberculosis, venereal disease, antenatal and postnatal conditions in women, and radiology. The Hammersmith Hospital has at present X ray and electrotherapeutic departments, a modern maternity ward with 16 beds, and an antenatal clinic. It has, however, no tuberculosis or venereal disease department and no organised out-patient department. The provision of these three departments must therefore be accepted as an inevitable part of the capital cost of converting the hospital into a post-graduate institution. There will also have to be a new nurses' home to accommodate 100 nurses at first, and capable of enlargement to take 200 or 250 nurses.

THE HOSPITAL BREAKFAST HOUR.—Warneford Hospital, Leamington, in response to the request of the majority of the staff and patients, has abandoned the new practice of washing patients and giving them breakfast at a later hour.

PRINCESS CHRISTIAN MATERNITY HOME.—Princess Helena Victoria, daughter of the founder, has opened an extension of this Windsor Home, an adjoining house having been purchased to provide additional accommodation. The King, who has hitherto made a grant of £100 a year from the State Apartments Fund, has increased the annual grant to £300.

Map showing on a scale of four inches to the mile the position of the Hammersmith Hospital and its accessibility by the Ealing extension of the Central London Railway with (at present) the nearest station of East Acton. St. Quintin Park Station connects with Kensington and Earls Court. Western Avenue is the new arterial road out of London.

PHYSICAL TREATMENT CENTRES.

To the Editor of THE LANCET.

SIR,—In his Milroy Lecture, reported in your issue of April 5th, Dr. Alison Glover alludes to the new Regent's Park Physical Treatment Centre, and also mentions the work of centres already existing in Kensington and Sheffield. He describes the Regent's Park Centre as capable of dealing with 400 patients a day. The Edgar Allen Institute, Sheffield, which covers a clinical field similar to that of the Regent's Park Centre, and which was inaugurated before the war, has for many years been called upon to treat considerably more than 400 cases daily; indeed, it has treated over 600 cases in a single day. In medical matters too much regard should not be given to arithmetical considerations; but in view of the fact that patients are only accepted at the Edgar Allen Institute on the advice of their own doctors, the figures given may be of interest as indicating the widespread demand for physical treatment.

I am, Sir, yours faithfully,

R. G. ABENCROMBIE, M.D.,
Medical Director, Edgar Allen Institute,
Sheffield.

April 11th, 1930.

"THE BLOOD PICTURE AND ITS CLINICAL SIGNIFICANCE."

To the Editor of THE LANCET.

SIR,—The review of Prof. Schilling's book which appeared in your issue of April 5th (p. 754) may be not unfairly critical of the English translation or even of the original German edition. But as one who is at present working with Prof. Schilling I should like to be permitted the opportunity of mentioning a few points which may help to allow a clear conception of this work to be formed.

The method of blood examination described has been for many years and is the routine method in use here at the Charité in Berlin, in the majority of the teaching hospitals and private clinics, and in the consulting rooms of many physicians in Germany. The method is simple and briefly is as follows: Two clean slides are taken—on the one, two thick smears are made, each consisting of three to four drops of blood, on the other slide a normal thin blood smear is made. In routine practice these are taken home and allowed to dry. Then the thick-drop preparation is stained with Giemsa reagent, the film is fixed with alcohol and then stained. The thick-drop slide is examined under the microscope for eosinophil leucocyte cells, for polychromatic erythrocytes, the remnants of which are visible as delicate blue networks lying between the leucocytes. They are present almost without exception in cases of anaemia, but are rarely found in normal adult blood. Net-forms, torn net-forms, and dot-like dissolution (basophilic punctation) are noted, and considered as evidence of toxicity. The coarser forms are of value in the diagnosis of lead poisoning. The stained film then is taken, examined under the low power of the microscope, and an approximate estimation of the number of erythrocytes made with special attention to their size, intensity of colour, and shape. The leucocytes in a few fields are noted and classified as to whether they appear in normal ratio to the erythrocytes, markedly decreased in number, somewhat increased or greatly increased. In practice after examining a few films, one can judge the number of leucocytes so that the estimate should not differ from that of a full leucocyte blood count by more than 2000 to 3000 per c.m.m. Then under the high power a differential count of 100 leucocytes is made.

Four fields are taken and 25 cells counted in each field. They are noted on a special chart under the heading of basophils, eosinophils, neutrophils, which are divided into myelocytes, juvenile, "stab," and segmented forms, lymphocytes and monocytes. The percentage count of the various forms of cells is taken and unless special abnormalities have been found, such as marked poikilocytosis, anisocytosis, &c., denoting a severe anaemia in which a full red cell count and haemoglobin percentage estimation is suggested, the routine examination is concluded.

The smears take but five minutes to make; the films can be stained at any later time, and then within half an hour, and the blood count takes ten minutes. This method gives the clinician a good indication of the blood picture at the time of examination and in practice is done frequently and where in the majority of cases a full blood count would not have been undertaken. It is not possible for me to discuss here the value of the blood picture, but the presence of eosinophils as seen in the thick drop or the presence of many juvenile or stab neutrophils, a shift-to-the-left (Arneht), suggesting a rapid severe regenerative process often without any evidence of a leucocytosis is of value in the diagnosis of an obscure sepsis or the course of an infective process.

In brief, Prof. Schilling has made practical a method of blood examination that can be carried out in routine practice. The blood sedimentation test is carried out as a routine by the ward clerks, as are the blood counts. It is a simple method, and is recognised as of undoubted value in the recognition of active pyogenic infection, of neoplasms, and repeated estimations are of especial prognostic value, for example, in watching the course of an individual case of pulmonary tuberculosis. The guttadiaphot is as yet in the experimental stage. Personally I am investigating certain aspects of rheumatic diseases, and I feel this method of blood examination may be of value in giving further evidence on which, at a given time, the diagnosis of activity or inactivity of an infective process may be made.

I am, Sir, yours faithfully,

FRANCIS BACH, M.D. Oxf.,
Chadwick Travelling Scholar.

The Charité, Berlin. April 7th, 1930.

CLINICAL RESEARCH.

To the Editor of THE LANCET.

SIR,—“M.D., F.R.S. Edin.” has mistaken my meaning when I said “there seem to be several equally effective methods of treating the same disease,” and perhaps he will be kind enough to read the letter again. Or possibly from his own experience he can tell us whether chemotherapy, rectal permanganate, specific vaccines or, what I recently witnessed, keeping the patient drunk with brandy, is the best way of treating pneumonia. Treatment is the primary business of the general practitioner for three reasons: first, because it is the patient's one and only object for coming to see us at all; secondly, because, although we see a good many cases each day, we see each patient several times, and diagnosis is only necessary the first time; and, thirdly, because diagnosis is easy in the majority of cases, or has already been made for us by a consultant.

It is always possible to recall straightforward cases where other men have made a wrong diagnosis. I myself recently saw a man with tabes who had been treated for three years, by a colleague whom I respect, for sciatica; and there are few pleasures in life equal to that of pulling the mote out of our brother's eye. But if that colleague were to take over my practice I have little doubt he would find a beam in my own eye. The reason for such an error is inherent in human nature; my colleague knew as much or more about tabes than I do, but when he first saw the patient the disease was too slight to be recognised, and the patient usually denies infection unless he thinks the

doctor has already found it out for himself. A tentative diagnosis is made and the pains are alleviated by a simple remedy; the working hypothesis gradually becomes fixed in his mind; "trifles light as air" become "confirmations strong as proofs of Holy Writ." Nothing is so difficult as to review a case one has treated on and off for several years. But by the time the patient gets to Doctor No. 4 the diagnosis is obvious to a fourth-year student.

Nervous diseases are the happy hunting ground of the diagnostician; but they are quite exceptional in general practice, and we can easily recognise them as out of our ken (if that is the case) and send them to a consultant, who will rejoice exceedingly if he finds an "organic" disease; if it is "functional" he will treat it with contempt and leave us to treat the patient, quite oblivious of the fact that functional disease is much more serious to the sufferer than most organic diseases; true, he may not die of it, but he makes life a misery to himself and others; which is worse.

I ended my letter by suggesting that an attempt be made to discover which are the common diseases and that they be studied first.

I am, Sir, yours faithfully,

FREWEN MOOR, M.D.

Westgate-on-Sea, April 10th, 1930.

Obituary.

PEVERELL SMYTHE HICHENS, D.M. OXF.,
F.R.C.P. LOND.,

CONSULTING PHYSICIAN TO THE GENERAL HOSPITAL,
NORTHAMPTON.

THE news of the death of Dr. Hichens, which occurred on March 28th, came as a great sorrow to his many friends. Since his retirement from practice in 1924 he had lived in Guernsey and for the last 18 months was increasingly an invalid.

Peverell Smythe Hichens was born at Speldhurst, Kent, in 1870, the second son of the Rev. Canon F. Hichens, rector of St. Stephen's, Canterbury, his elder brother Robert being the novelist. He was educated

at King's School, Canterbury, Clifton College, and Magdalen College, Oxford. From there he went to St. Thomas's Hospital in 1892, and took his B.M. at Oxford in 1895. After demonstrating pathology and surgery, and holding resident appointments at his own hospital and at Brompton, he developed symptoms of lung trouble and spent a year or more at Nordrach, in the Black Forest, where Otto Walther's methods were

DR. HICHENS.

just beginning to attract attention. In 1901 he was appointed physician to the General Hospital, Northampton, and soon acquired a good consulting practice in the town and country. In 1903 he took his D.M. at Oxford; and in 1911 was

elected a Fellow of the Royal College of Physicians, having been a Member since 1899. His interest in tuberculosis was quickened by the honourable mention he obtained for his essay for the King's Sanatorium Prize in 1902, and in the following year he published an important paper on sanatorium treatment with special reference to Nordrach methods, with which a prolonged personal experience had made him familiar. At once he began to awaken local interest in the foundation of an institution for the open-air treatment of tuberculosis and his efforts were finally crowned with success when, in 1909, the county sanatorium was opened at Creton and he was appointed its consulting physician. Of his work an old colleague at the hospital writes: "I know how sound Hichens was in his judgment of a case and how conscientious and painstaking he was in anything he undertook. I think he liked sometimes to regard himself as old-fashioned and to affect a regret that the art of medicine was becoming increasingly complicated by fresh methods and fresh discoveries. Of these, however, he was always among the first to make use." His war service was distinguished. Under the old territorial hospital scheme he was a major attached to the 1st Eastern General Hospital at Cambridge, but he quickly managed to exchange from this into a field ambulance and got to France in 1915. There he was in command, first of a casualty clearing station and subsequently of a general hospital at Calais. He was not demobilised until the summer of 1919.

His chief interest outside medicine was in the Church and all the time he was in Northampton he did a great deal of hard work as vicar's warden at All Saints' Church. He was a man of considerable general culture. He read constantly and knew his English literature well; he had a wide knowledge of music and was a good pianist, while every holiday produced some charming water-colour sketches. The same colleague writes: "I always think of him as rather old for his years. This may have been due to a slightly pedantic manner, but with this was combined a constant kindly courtesy which made him liked and respected by everyone with whom he came into contact."

In 1906 Dr. Hichens married Constance, daughter of Lieut.-Colonel L. Downes, and he leaves a widow, a married daughter, and a son

HERBERT JAMES ILOTT, M.D. ABERD.

Dr. H. J. Iloft, who died at Midhurst on April 3rd at the age of 77, was formerly one of the best known practitioners in Kent and came of a medical family which has been associated with Bromley for over 200 years. His ability was early shown by his achievements as a student at St. Bartholomew's Hospital, where in 1872 he was senior scholar in medicine, surgery, and midwifery, and in 1873 won the Kirke's gold medal for clinical medicine. A year later he graduated at Aberdeen with highest honours, and after a period as house surgeon at Croydon General Hospital settled down in the family practice at Bromley. Here the remainder of his professional life was spent, and it was not until a few years ago that he retired and went to live at Midhurst. He was lately elected Master of the Society of Apothecaries, but failing health prevented him from undertaking the duties.

Dr. Iloft leaves a widow, with a son and a daughter.

COVENTRY AND WARWICKSHIRE HOSPITAL.—The number of in-patients increased last year by nearly 300, and out-patients were more numerous by over 2000. In 1910 there were 1433 in-patients; last year the number was 5099. At £6 17s. 10d. last year the average cost of an in-patient was 6s. 3d. less than in 1928. The cost of each patient at the Alcock Convalescent Hospital (average stay 17.5 days) was £4 6s., an average of 4s. 10d. per day.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

MENTAL TREATMENT BILL.

On April 11th the House of Commons considered the Mental Treatment Bill on report.

Power to Receive Voluntary Patients.

On Clause 1, Dr. VERNON DAVIES moved to delete from the first Subsection the words "for mental illness." He said that the elimination of these words would not have a detrimental effect on the Bill, and would simply bring it into line with the Lunacy Act. He thought that the amendment would have a very material effect in encouraging people to come at the earliest moment to submit themselves to treatment.

Mr. GREENWOOD (Minister of Health) said there was nothing derogatory in describing in a Bill the plain fact about the disease from which a person was suffering. They must define diseases, and there could not be any words less objectionable and more neutral than the term "mental illness." There was a difference of medical opinion on this matter, as was shown in Committee, and therefore it was better to retain the words. He did not think that voluntary patients would be deterred by them from seeking treatment. Already they went in large numbers to these institutions. The amendment was negatived.

The Board of Control and the New Service.

Mr. KINLEY moved an amendment to disassociate the Board of Control from any connexion, direct or indirect, with the new service for the treatment of voluntary patients, and to substitute for the Board the Minister of Health. He said that the amendment was of fundamental importance, and on the decision of the House upon it would depend whether the Bill would be of real value to the public. He (Mr. Kinley) was whole-heartedly in favour of this new public health service for the prevention of lunacy, but he held that the Board of Control should have nothing whatever to do with it, otherwise it would be doomed to failure. The Board of Control have been condemned in the public mind for many years, and that condemnation had been lately justified because the Royal Commission had stated that the Board as hitherto constituted was not worthy of continued existence. Fundamental alterations in the constitution of the Board were proposed in this Bill. He did not say that the individuals who comprised the Board of Control had been responsible for the failure, but he did suggest that the record of their work so far as they could ascertain from statistics proved that if there was one thing that was important in their public health service it was that the Board should not be permitted to enlarge its scope until it could prove to the nation by results that the power it possessed had been well used. From all that he could discover there was no justification for any statement that the Board had been successful. He was amazed that long before now there had not been a minute and severe investigation into the whole of the operations of the Board. In answer to questions addressed to the Minister of Health during the last few weeks he had ascertained that on the average 22,000 people were admitted to asylums every year, and that over 30 per cent. of these were recorded as deaths within 12 months. Over a period of ten years out of the 22,000 admitted each year, 10,000 were discharged, and 8000 or 9000 died. Over the same period the number of suicides had increased from 49 in the first of the ten years to 61 in the last year; another reason sufficient to condemn the Board of Control. According to a reply given to him only a week ago by the Minister of Health, in the publicly owned institutions the patients had the advantage of the service of a resident medical officer to the extent of one doctor for 280 patients. Under no circumstances could the arrangement ever give the results that they were entitled to demand.

Mr. MESSER, in seconding the amendment, said that the Board of Control had outlived its usefulness at least in the eyes of the public authorities who had been appointed under the Ministry of Health to discharge the functions necessary in dealing with mental cases. The Board was necessary in the days when private institutions were the only ones dealing with cases of this kind, and when it was necessary in the public interest that there should be close examination of all complaints concerning institutions for mental treatment. But as time had gone on county councils had found the Board of Control not a help, but a hindrance.

Sir KINGSLEY WOOD said there was not a word in the report of the Royal Commission to support the rather

reckless statements that had been made that day. The proposal of the amendment to substitute the Minister of Health for the Board of Control in regard to these voluntary mental patients involved considerable administrative difficulty. It would mean a duplication of machinery and of staffs which would be very unfortunate unless there was overwhelming necessity for it. He thought that the Board of Control would give a measure of protection to the persons who took advantage of the treatment under this Bill. He hoped that it would be possible for the Minister to retain the lay element on the Board of Control, as it would strengthen the Board in the eyes of the public.

Colonel WEDGWOOD begged the House to consider that the liberty of the subject was one of the most sacred charges upon every Member of Parliament. Every British citizen should have at least some appeal to a court to escape from the control of the expert and the bureaucrat.

A Defence of the Board.

Dr. MORRIS-JONES said that Colonel Wedgwood objected to mental patients being treated by an expert. Who did he suggest should treat them? The right hon. gentleman, he assumed, to save his life would submit to a grave operation at the hands of a surgeon, but he would not trust a medical commissioner in lunacy.

Colonel WEDGWOOD: I should choose my own surgeon.

Dr. MORRIS-JONES said that liberty, after all, was a limited matter, and he was sorry to hear the very strong remarks that had been made about the Board of Control. He realised that Mr. Kinley had moved this amendment quite sincerely, but he suggested that it was entirely misinformed and misguided, and he had made references to a body which was doing very difficult work which were not worthy of his work during the committee stage. The Board of Control were dealing with thousands of people, not one of whom was normal mentally, and he (Dr. Morris-Jones) thought they had done their work extraordinarily well in the circumstances. Their name was unfortunate. The British people did not like the word "Control," and it was very unfortunate that in 1913 they were given the name of "Board of Control." He would read to the House the views of a great expert, Sir Maurice Craig, on the Board. Sir Maurice had stated:—

"I am aware that there is a diversity of opinion as to who should be the authority responsible for supervising patients in the early stages of mental disorder. For many years I felt, with others, that the Board of Control were too much steeped in the traditional treatment of mental disorder, and that it might be difficult for them to free themselves from this outlook, and in consequence I feared it might, in practice, be difficult to have the body visiting patients who are not insane. But it has been impossible to watch the work of the Board of Control during recent years without appreciating how much they have taken up the more modern views of psychological medicine, indeed, they have shown such power of adapting their functions to the medical outlook and I am now of opinion that this body is fitted to undertake the supervision of all mental patients, including those in the early stages of illness."

That was an unbiased opinion. This was the conclusion which the Royal Commission came to in regard to the Board:—

"We are satisfied that the criticisms to which this Department has been subjected are to a large extent ill-informed, and that where criticism is justified the cause is to be found rather in the existing system than in any want of zeal on the part of members of the Board. Having had opportunities of observing the care and thoroughness with which their work is done and the wide scope of their activities and their vigilance, we think that the Board have discharged their duties under the present code in a manner deserving of great commendation; but they are handicapped by three factors beyond their control."

That was a very fitting and unimpartial testimony to the Board of Control. Voluntary patients under this Bill would gain tremendously from the protection afforded by the Board of Control. It was amazing to him that the Board should be so constantly assailed on all sides. He was sure that they were quite prepared to go on doing their work conscientiously in spite of any criticism. He (Dr. Morris-Jones) had great hopes for Clause 1. Medical men would make great use of it, and try to get patients voluntarily to seek early treatment.

Non-Certifiable Treatment for the Masses.

Mr. GREENWOOD said that Clause 1 did not represent the views of bureaucrats or experts, but the conclusions of the Royal Commission. The voluntary patient had existed under the law for a considerable time, and all that they were trying to do in this Bill was to render this early form of non-certifiable treatment, which at present was available only for the well-to-do, available also for the mass of the people. The experience of the voluntary patient system in the past showed that the Board of Control had really not been a force working against the success of the system. During 1929 there were admitted to registered hospitals 662 certified patients and 698 voluntary patients. In the

case of licensed houses, 974 certified patients were admitted and 757 voluntary patients. The point was that nearly one-half of the entrants into registered hospitals went in voluntarily. Therefore, there was not in the minds of these people that fear which had been suggested. By this amendment the House was not asked to abolish the Board of Control, or to supersede it by the Ministry of Health. That would require a very far-reaching Bill drastically amending the principal Act of 1890. Obviously that could not be done in this Bill, particularly at the present stage. What the amendment asked was that the Ministry of Health should be directly responsible for certain aspects of mental illness, whilst retaining the Board of Control for the major portion of the responsibility for such illness. That would mean that in most cases there would be going to the same institutions medical visitors of the Board of Control and of the Ministry of Health. There would be duplication of inspection and of administration. The problem was more complicated than that. Hon. Members must not suppose that the voluntary patient was in a category which was unalterable, or that if he came under Clause 5 he would always remain so, or that if he was certified he was certified for ever. These three categories of persons were ever-changing. Mental disease took many forms; it was more acute in some cases than others, and one form passed into another. It seemed to him bad administration to take one particular category of people suffering from mental illness and to say that they should be supervised by the Ministry of Health, and that the other categories should come under the supervision of the Board of Control. What were they going to do about the people who oscillated between one category and another? Hon. Members were asking for an administrative system which no Minister would pretend to work, because it would be utterly impracticable.

Mr. WATERSLEY asked the Minister whether he would accept an amendment giving the local authorities a right of appeal to the Minister of Health against any decision of the Board of Control?

Mr. GREENWOOD: On that matter I stand precisely where I stood during the Committee stage.

Mr. BECKETT said that during the six years he had been a Member of the House he had been brought into touch with the Board of Control on a great number of occasions, and he could not remember a single case in which he had felt satisfied when the case was finished that the right thing had been done. He could not remember a case where the correspondence from the Board was, in his opinion, fair, honest or candid. His experience was that the Board always sought to detain persons under their control. In one case he was able to trace all their lies, their malevolence, their libellous statements and their maliciousness. He took the matter to the Ministry, and finally, by threats of publicity, he was able to get an apology. A case like that left a very uncomfortable feeling in the mind that in many cases in which he had failed, had he been able to get as much information as he did in this case, and had the Board of Control made one little slip in their facts, as they made in this case, he might have been able to do much more. His experience of the Board of Control had convinced him that it was permeated by the very worst type of charity organisation mentality. He wished they could have got the Minister to meet them on this point. No one said that this Bill was unnecessary; it would do a lot of good, but it was giving increased power to a body over which the House had no effective control, and in which a great many Members had no confidence.

Dr. VERNON DAVIES said that they had listened to a rather unfortunate speech in which a Member of the House had thought it necessary to make a distinct and deliberate charge against the Board of Control. The Board could not answer for themselves, and although he had no love for officials as a class, and believed that there was a great deal to be said against the introduction of a new despotism, he did not think that officials should be subjected to a charge in that House unless the Minister was given an opportunity to reply. He (Dr. Davies) could not agree to this amendment because one of his principal objections to the Bill was that it lowered the status of the Board of Control. Certain hon. Members seemed to have a wrong idea of the functions of the Board. It could almost be described as a judicial body. They acted as judges on all documents or medical certificates to see that they were absolutely in order. They were the guardians of the liberty of the subject. The power of a body like that should, if possible, be increased. To reduce them in status, as was being done under this Bill, by placing them under the Minister of Health, weakened their position. They would simply become a department of the Civil Service. He went further and said that they would have a new tyranny. If Members asked a question the Minister of Health would only tell them what he wanted them to know, or what his department wanted them to know.

The amendment was negatived by 205 votes to 18.

Mental Hospitals and Voluntary Patients.

Mr. WINTERTON moved an amendment to provide that unless a voluntary patient was of unsound mind within the meaning of the Lunacy Acts 1890 to 1922, he should not be received as a patient, either rate-aided or paying, in a public mental hospital. He asked whether the Government or anyone else who supported this Bill suggested that an ordinary lunatic asylum was the proper place in which to treat these patients? THE LANCET had said a little while ago: "If a person with mental disturbance voluntarily asks for treatment in a hospital or home, why should he more than any other invalid have to be notified to the Board of Control?" There seemed to be no ground whatever for saying that a voluntary patient should be treated in exactly the same way as a hopeless lunatic.

Mr. BROCKWAY seconded the amendment.

Miss LAWRENCE (Parliamentary Secretary to the Ministry of Health) said that these patients could no more be "sent" to any place than any Member of Parliament. They were not lunatics, but people who were a little worried about themselves, and they went into the institutions which dealt with all classes of cases, varying from lunacy to the mildest form of mental worry. There was no clear-cut distinction between a case of hopeless melancholia and a person who had become depressed. If that were so, what was the sense of saying that the same institution should not be allowed to treat the extreme forms of a disease and the mild forms of the same disease? She thought it very likely that, with the enormous amount of fresh institutions coming into the hands of the local authorities, where public opinion would allow it they might set apart separate buildings if they found a reluctance on the part of voluntary patients to go into the other mental institutions. But at present people did go to the mental hospitals.

Dr. VERNON DAVIES said at the present time there was no other accommodation for these patients except the mental hospitals, and though he was bitterly opposed to sending them to those hospitals, which were already overcrowded, he recognised the difficulty. Pressure must be exerted on the local authorities to supply other places for these people. Under the new Local Government Act, the borough or county councils could establish convalescent homes for these cases where they could be free from the ordinary asylum environment. But, of course, they would have to be under the care of a medical man with some experience of the subject. At present, however, they must include the mental hospitals as places for the accommodation of these cases.

Lieut.-Colonel FREMANTLE supported the views put forward by Miss Lawrence and Dr. Davies.

The amendment was negatived.

Notice of Reception, Death and Departure of Voluntary Patients, and Provisions as to the Discharge of Patients.

On Clause 2, Colonel WEDGWOOD moved an amendment which proposed to qualify the reference in Clause 1 to persons becoming incapable of expressing themselves as willing or unwilling to continue to receive treatment by requiring that they should be so incapable "in the opinion of a magistrate."

Mr. GREENWOOD said that he was in favour of the exclusion of magisterial interference to the greatest possible extent. The real objection to the intervention of a Justice of the Peace was that it had always been associated in the public mind with certification.

The amendment was negatived by 192 votes to 30.

The further consideration of the Bill on Report was adjourned.

POST-GRADUATE MEDICAL STUDY.

In the House of Commons on April 9th Mr. NEVILLE CHAMBERLAIN asked the Minister of Health what action the Government proposed to take on the Report of the Post-graduate Medical Education Committee.

Mr. GREENWOOD (Minister of Health) replied: In view of the public interest in this matter I hope that the House will permit me to make a statement which exceeds the usual limits of a reply to a question. The Committee was appointed by my predecessor. He was as Minister of Health its chairman and I succeeded him. The Report will be in the hands of Members to-day. The proposal of the Committee is that in order to remedy the most serious outstanding defect in the existing provision for the education in medicine of post-graduate students, a British Post-graduate Hospital and Medical School should be established in London.

Organisation and Financial Position.

The organisation of the British Post-graduate Hospital and Medical School recommended by the Committee consists

of an existing public hospital, the Hammersmith Hospital, with 400 beds in modern wards, which on April 1st became the property of the London County Council under the Local Government Act, 1929; a medical school in conjunction with the hospital; and a residential hostel on a site in central London. The Committee estimate that the financial provision required to establish and maintain the British Post-graduate Hospital and Medical School, apart from the cost of the maintenance of the beds in the public hospital, which in their view should remain, as it is now, a charge on the ratepayer, will be as follows: First, a capital sum not exceeding £250,000 for building a medical school, which together with the hospital will form the main part of the new organisation, and for providing educational equipment. Secondly, the sum necessary to maintain the medical school as a recognised school of the University of London. Thirdly, the capital cost of building the residential hostel. The Government have accepted the recommendations of the Committee as to the organisation of the British Post-graduate Hospital and Medical School. They are much impressed with the importance of securing without avoidable delay the advantages of a proper system of post-graduate medical education in London, not only from the domestic, but also from the Imperial and from the international points of view. The Government will, accordingly, be prepared to contribute from public funds a maximum sum of £250,000 for building and equipping the medical school as an integral part of the scheme recommended by the Committee, and to make provision for grants through the University of London towards the maintenance of the school on the lines already applied to comparable institutions of university rank. The Government earnestly hope that they may secure the co-operation of the London County Council and of the University of London in the scheme as recommended by the Committee, and they are entering into communication with those bodies on the subject.

"London House."

The Government understand that an appeal will shortly be made to the public for assistance in the establishment in London of a residential institution to be called "London House" for the use of students from the Dominions not only in medicine but in other arts and sciences. It is also part of the proposed scheme that "London House" shall offer accommodation to a limited number of British students domiciled in Great Britain and Northern Ireland in order to furnish collegiate association between them and students from the Dominions. Such an institution would, in fact, secure the object aimed at by the Post-graduate Medical Education Committee in recommending the provision of a hostel. The Government are in full sympathy with the movement and they look forward with full confidence to the success of the appeal which it is made as crowning a scheme to which the taxpayer, the ratepayer, and the general public will be contributing their appropriate shares.

Expansion if Required.

Mr. CHAMBERLAIN: I am sure that the statement which the right hon. gentleman has just made will give profound satisfaction as soon as its full implications are appreciated. In congratulating him upon the final success—which I am sure he will agree is largely due to the very distinguished body of surgeons and physicians constituting the Committee—may I ask him whether the hospital which has been chosen is considered to have a sufficient number of beds for the purpose for which it is required, and whether, if not, there is room for extension if it is considered desirable?

Mr. GREENWOOD: Yes, Sir. The scheme envisaged by the Committee makes provision for a larger number of beds than is now available at Hammersmith. The Committee were unanimous in their choice of Hammersmith, and there is sufficient available ground for extension and the number of beds to make the hospital effective.

Mr. MARLEY asked whether it was proposed that colonial students as well as students from the Dominions would be able to reside at "London House," as there were post-graduate students from Africa taking courses in tropical medicine?

Mr. GREENWOOD: If I used the term Dominions narrowly I am sorry. The hostel will be available for students from all parts of the British Commonwealth.

In answer to Miss RATHBONE, Mr. GREENWOOD said that men and women would both be included in the scheme, but the scheme was intended for post-graduates and not for ordinary students. It was to assist people who already possessed qualifications.

Miss RATHBONE: Does the right hon. gentleman not think it likely that women students will be included among post-graduate students?

Mr. GREENWOOD: Yes, certainly.

HOUSING (SCOTLAND) BILL.

On April 10th, Mr. ADAMSON (Secretary of State for Scotland) in moving the second reading of the Housing (Scotland) Bill, said its object was to secure that the slums of Scotland, which had long been a standing reproach, should be done away with, and that in place thereof there should be houses of adequate size in which healthy, happy lives could be lived. The report of the Royal Commission on Housing in Scotland, which was issued in 1917, revealed a picture of the housing conditions in Scotland as a whole which showed unsatisfactory sites of houses and villages, insufficient supplies of water, unsatisfactory provision for drainage, inadequate provision for the removal of refuse, widespread absence of decent sanitary conveniences, houses in many of the mining areas badly constructed, incurably damp labourers' cottages on farms, whole townships unfit for human occupation in the crofting counties and islands, and primitive and casual provision for many of the seasonal workers. That Commission recommended that there were required in Scotland 121,430 houses to meet the needs of the people.

The Commission were not satisfied, however, with the standard of housing accepted at the time of their report, and they were strengthened in that opinion by a reference to the census figures which showed that half the houses in Scotland were of one and two rooms only. They recommended, therefore, the raising of the standard, and to achieve this it was estimated that an additional 114,660 houses were required or a total of 236,090 houses before the people of Scotland could be regarded as adequately housed. Each Government since the issue of the Commission's report had made its contribution to the solution of this problem, and although up to Feb. 28th last, the latest date for which returns were available, there had been provided under all forms of State assistance by local authorities and private enterprise a total of 107,451 houses. As it was estimated that 10,000 houses were required annually in Scotland to meet the normal needs and to provide for the new yearly demands, it would be realised that since 1919, when the first scheme of Government assistance was passed by Parliament, building operations had, on the average, only just kept pace with the normal needs of the Scottish people.

The Problem of the Slums.

However commendable the efforts of the local authorities up to date had been, the houses built had not succeeded to any extent in solving the problem of the slums, or the housing of the poorer section of the community. Some steps, however, had been taken in that direction with the aid of the 60 per cent. grant under the 1923 Act, and 11,205 houses had been built at low rents, specifically to take the place of houses which were occupied, but were unfit for human habitation. This, however, was only a small contribution in comparison with the magnitude of the problem. In 1919 the local authorities in Scotland estimated that 34,765 houses were required to replace houses that had to be closed, while 41,880 houses were required to relieve overcrowding. Recent available figures indicated that there were at least 13,000 houses occupied in Glasgow that should be closed; in Edinburgh over 5000; in Greenock about 14,000; in Dundee about 2000; and in Aberdeen about 1500; besides a large number in other parts of the country for which he would not attempt to give figures. Overcrowding was not confined to what were generally known as slum areas; it was just as common outside those areas; and in the interests of health, decency, and morality, its mitigation was essential. According to the latest census returns more than 2,000,000 persons in Scotland, or over 43 per cent. of the population, were living more than two in one room.

Re-housing Grants.

The Bill proposed that grants should be given not only for the re-housing of persons displaced by the closing of uninhabitable houses, but also for those displaced by the operations of a local authority to abate overcrowding. The Government proposed to work through the local authorities, who would be given State assistance. Experience had shown that certain improvements in the machinery for clearing slums were necessary, and the Bill embodied those improvements. It was necessary to separate the clearance procedure from the development procedure, and this constituted the main difference between the procedure under the present law and that proposed under the Bill. Part I. of the Bill dealt with the clearance or improvement of unhealthy areas. Part II. dealt with the repair, its mitigation, or closing of insanitary houses. Under Part III. local authorities were required to consider the housing needs of their district from time to time, and as occasion arose, to submit proposals to the department for the provision of new houses. The financial proposals contained in Clauses 10 to 21 substituted for the present percentage grant a new

with an income, all from investment, not exceeding £185, or with an income, all earned, not exceeding £582, there would be no increase in the income-tax bill. The same was true in the case of a married man with three children unless his income from investment exceeded £735, or, if earned, it exceeded £882. Income-tax payers talked as if they paid 1s. in the £ on all their incomes, but out of 2,250,000 income-tax payers there were not 50,000 who paid the full standard rate of 1s. No person with an income below £3000 paid the full rate, and the great majority did not pay more than from a few pence to 2s. in the £. As regarded life insurance, the old rates of 2s., 3s., and 4s. would remain unchanged. The extra 6d. on the income-tax standing alone would produce about £29,000,000 in a full year. Allowing for the cost of change in graduation (£5,000,000 in a full year), the yield would be about £24,000,000 in a full year and £21,000,000 in the current year. As regarded the surtax, he proposed to correct an anomaly by placing it on the basis that the rate of tax payable in any year would fall to be determined by the financial needs of that year. The increase in the standard rate of income-tax would, of course, be borne by surtax payers as well as other income-tax payers. But the financial needs of the current year were such that he felt bound to call upon the surtax payers to supplement the additional payment of income-tax by an additional surtax. He proposed an increase in the initial rate from 9d. to 1s. in the £, and in the case of incomes over £50,000 an increase from 6s. to 7s. 6d. This would yield £12,500,000 in a full year and £7,500,000 in the current year. The capital now coming under charge to estate duty had now passed £500,000,000, and the yield of estate duty had reached £70,000,000. For estates exceeding £2,000,000 he proposed to increase the rate from 40 per cent. to 50 per cent. Amendments would be made to the existing scale from £120,000 upwards by increases of 1 to 2 per cent. from £120,000 to £250,000, with a growing increase from £250,000 onwards to reach a rate of 50 per cent. on estates exceeding £2,000,000. He expected that the yield would be about £7,000,000 in a full year and about £3,000,000 in the current year. The total effect of the changes in income-tax, surtax, and estate duty would be a yield of £31,500,000 in the current year and £43,500,000 in a full year.

Land Values—Safeguarding Duties.

As a first step to the levying of a contribution upon land values he was taking steps to prepare a valuation of all sites in the country. A separate Bill would be introduced to provide for this valuation. The £10 duty on betting certificates would be repealed as from the end of October. This would cost about £200,000 in a full year and about £180,000 this year. Four safeguarding duties under the existing law were due to expire this year—namely, lace (June 30th), cutlery, gloves, and gas mantles (Dec. 21st). The duties would be continued till these respective dates but would not be renewed. The cost was estimated at £521,000 this year and £823,000 in a full year. The Finance Bill would contain minor relief from stamp duties as they affected certain schemes of rationalisation and amalgamation. The cost would be £250,000. Small alterations proposed last year affecting motor-cycles, commercial motor vehicles between 2 and 2½ tons, and petrol electric vehicles, would take effect on July 1st in the first two cases, and on Jan. 1st in the last case. The cost would be £20,000 a year to the Exchequer and £90,000 a year to the Road Fund. The beer duty would be raised as from April 15th by 3s. per standard barrel, leaving rebate unaltered. This amounted to an increase of 1d. per gallon which was too small to justify an increase of price and the brewers had given assurances that there would be no drop in gravities. The yield would be £3,100,000 in a full year and £2,750,000 in the current year. Legislation would be proposed (a) to prevent (1) avoidance of estate duty on landed estates and investments through the medium of private companies; (2) avoidance of surtax by single premium insurance policies; and (b) to give revenue authorities rather wider powers of obtaining information in regard to ownership of income. Provisions would be made for a new assessment of all property in Great Britain for income-tax Schedule A. This would come into force for next year 1931–32, and would include the metropolis. From 1931–32 the reassessment would take place automatically at quinquennial periods. Minor provisions would be made to deal with points of hardship, or to make slight readjustments in the inland revenue duties.

National Finance.

Reviewing the national finance for the past year, Mr. Snowden said that there was an actual deficit of £14,523,000, instead of an estimated surplus of £4,090,000. Expenditure exceeded the original estimate by £6,748,000. The total national expenditure for 1930–31 (excluding self-balancing items) was estimated at £781,909,000. If provision was made for the deficit of 1929, and for a small adjustment in respect of Northern Ireland's share of the increased

taxation, the total was £787,209,000. The estimated revenue was £739,645,000. The lapse of the safeguarding duties was allowed for in the estimate of £250,000,000 for customs and excise. Other minor changes involved a loss of £150,000. The increase in the beer duty, increase of direct taxation, and the Suspensory Fund would bring the total revenue up to £780,415,000, leaving a surplus for contingencies of £2,230,000.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 9TH.

Tannic Acid Treatment for Burns.

Dr. VERNON DAVIES asked the Home Secretary if the senior medical inspector of factories had reported to him on the tannic acid treatment for burns; and, if so, what decision had been arrived at with regard to its use in factories and workshops.—Mr. SHORT (Under Secretary to the Home Office) replied: Yes, Sir. My right hon. friend has received a report from the senior medical inspector. His conclusion, reached after careful inquiry, is that this form of treatment is not suitable generally for the first-aid treatment of burns at a factory or workshop. It can only be properly given in works where there is an ambulance room properly equipped and in charge of a properly qualified person, and in the treatment of minor burns it has no advantage over sterilised burn dressings. In the case of severe burns it may be valuable where the patient cannot be moved to hospital without considerable delay, but otherwise the protection of the burn by a simple dressing is the proper procedure. He does not therefore advise any modification of the existing instructions.

Dr. DAVIES: Will the hon. gentleman inform the Home Secretary that there is a very large body of medical opinion which totally disagrees with the advice that has been tendered to him?

Mental Patients and Suicide.

Mr. KINLEY asked the Minister of Health the number of cases of suicide and attempted suicide, respectively, which occurred in each of the past ten years in institutions under the jurisdiction of the Board of Control.—Mr. GREENWOOD replied: The Board of Control have no information in regard to cases of attempted suicide. In mental deficiency institutions suicidal acts are extremely rare. The annual reports of the Board of Control state each year the number of patients who have died in institutions for the insane as a result of suicidal acts committed either while in residence or on leave or before admission. The figures for the last ten years are as follow: 1920, 47; 1921, 45; 1922, 52; 1923, 39; 1924, 44; 1925, 47; 1926, 65; 1927, 69; 1928, 64; 1929, 61.

Staffs of Mental Hospitals.

Mr. KINLEY asked the Minister of Health the total of persons employed on staff duty during each of the past ten years in the institutions under the jurisdiction of the Board of Control.—Mr. GREENWOOD replied: The only figures available relate to the charge and ordinary nurses employed in county and borough mental hospitals. The numbers on Dec. 31st in each of the last ten years were as follow: 1920, 14,880; 1921, 15,439; 1922, 15,563; 1923, 15,824; 1924, 16,060; 1925, 16,460; 1926, 16,855; 1927, 17,262; 1928, 17,662; 1929, 17,748.

THURSDAY, APRIL 10TH.

Various Industries (Silicosis) Order.

Mr. HOLLINS asked the Home Secretary when he intended to introduce legislation to amend the Various Industries (Silicosis) Order; and whether he would include, within the amending Order, provision for compensation for partial incapacity due to silicosis.—Mr. CLYNES replied: Amendment of the Various Industries (Silicosis) Order to include cases of partial incapacity is dependent on the passage of the Bill which the Government have introduced to amend the provisions of the Act which relate to medical arrangements for examination and diagnosis. The Bill has already been read a second time in the other House, and it is my intention, as soon as it has passed, to take up the question of the amendment of the Order.

Birching in Borstal Institutions.

Mr. BENSON asked the Home Secretary who was the final authority to sanction birching in Borstal institutions.—Mr. CLYNES replied: Cases are very rare, only one since 1928; and when I replied to my hon. friend's supplementary question on March 31st I was under the impression that such an order would not require my confirmation.

Importation of Chemically-Treated Flour.

Viscount ELMLEY asked the Minister of Health if he would briefly indicate the nature of the regulations relating

to the importation of chemically-treated flour?—Mr. GREENWOOD replied: The only regulations are those contained in the Bread Acts of 1822 and 1830, the general effect of which is that no flour may contain any ingredient not being the genuine produce of corn or grain.

Tuberculin-tested Herds and Agricultural Shows.

Brig.-General CLIFTON BROWN asked the Minister of Health whether he had considered the representations made to him by the Royal Agricultural Society and other similar societies as to the order prohibiting tuberculin-tested herds from exhibiting at their shows; and whether he could make it possible for these societies to comply with his requirements by segregating the tuberculin-tested cattle at their shows.—Mr. GREENWOOD replied: I received a deputation from the Royal Agricultural Society and two other societies, and they informed me that they are unable at present to make the requisite arrangements for segregation. The prohibition must, therefore, stand so far as the shows of these societies are concerned, but I am prepared to consider its withdrawal in the case of any shows where satisfactory arrangements can be made.

Sale of Vitacream.

Mr. HANBURY asked the Minister of Health whether his attention had been drawn to the extensive sale of vitacream, which was seriously competing with the sale of genuine British cream; and whether he would consider the advisability of amending the law so that it should be sold under the designation of cream substitute with the analysis shown clearly on the parcels exposed for sale.—Mr. GREENWOOD replied: My attention has been drawn to the sale of this article, but I regret that I cannot undertake to introduce legislation on the subject at the present time.

New Town-planning Legislation.

Lieut.-Colonel FREMANTLE asked the Minister of Health if he still considered a further measure of town-planning essential to proper housing development; and whether he proposed to introduce legislation for the purposes.—Mr. GREENWOOD replied: It is still my intention to introduce amending town-planning legislation as soon as opportunity permits.

British Spectacle Frames and Ophthalmic Benefit.

Sir GEORGE PENNY asked the Minister of Health whether, in issuing fresh regulations regarding the administration of national health insurance through the approved societies, he would stipulate that spectacle frames dispensed under the scheme should be of British origin.—Mr. GREENWOOD replied: I will consider what steps I can take to encourage the use of spectacle frames of British origin in connexion with ophthalmic benefit under the National Health Insurance Scheme.

Welfare of the Blind.

Mr. TOM SMITH asked the Minister of Health if he was aware of the suggestion of the advisory committee on the welfare of the blind that the reduction of the age limit from 50 to 40 years for the receipt of a blind pension would be fully justified; and whether he proposed, in the near future, to take any action on the matter.—Mr. GREENWOOD replied: The answer to the first part of the question is in the affirmative. With regard to the second part, this matter is under consideration in connexion with others affecting the welfare of the blind, but I am not in a position to make a statement on the subject at present.

Death-rate from Tuberculosis.

Mr. KINLEY asked the Minister of Health whether there were any local authorities whose tuberculosis figures showed little or no decline during the past ten years; and whether he proposed to take any action in the matter.—Mr. GREENWOOD replied: There are a few areas in England and Wales in which there has been little or no decline in the death-rate from tuberculosis during the past ten years. The factors which may bear upon this matter are receiving special study in my department.

Health Insurance Benefit.

Sir KINGSLEY WOOD asked the Minister of Health whether he would make a statement as to the results of the recent investigation by the Government actuary into the claims experience of a representative group of insured persons; and what action he was taking as a result of such report.

Mr. D. G. SOMERVILLE asked the Minister of Health whether his attention had been called to the statement by the controller of the Insurance Department of the Ministry of Health to the effect that the growth of sickness claims was out of all proportion to the increase in the burden of unemployment, and that a complete explanation would have to be sought elsewhere; whether such explanation was being sought; and on what lines.

Mr. D. G. SOMERVILLE asked the Minister of Health if his attention had been called to the warning of his controller against malingering on the part of persons drawing benefits under the National Health Insurance Scheme; and whether he was satisfied that the standard of administration by every society concerned was sufficiently high to ensure that additional benefits were not sacrificed by laxity.—Mr. GREENWOOD replied: I am aware of the position with regard to the increase in expenditure on sickness and disablement benefits, which has been a matter of concern to me for some time past. The report of the Government actuary on the subject will be laid on the table of the House within the next few days. The causes of the increase are under investigation by the departments concerned, and steps are being taken to deal with any laxity which is brought to light.

Sir K. WOOD: Having regard to the grave anxiety among the approved societies, can the right hon. gentleman take any steps, for instance, in connexion with medical certification under the Act? Is there any possibility of improving that?

Mr. RHYS IEVES: Will the right hon. gentleman ask his staff to find out whether there is not a definite decline in the claims for the first quarter of this year compared with any previous period?

Mr. GREENWOOD: I cannot carry the figures in my head. I have only seen the results of the actuarial investigation in the last six days and I have not had time to examine them.

Mr. BUCHANAN: Before the right hon. gentleman takes any action will he consult the House, because the insured persons have rights equally with the approved societies?

Mr. GREENWOOD: The approved societies represent the members.

Slum Area in Tunbridge Wells.

Dr. PHILLIPS asked the Minister of Health whether any scheme had been placed before him by the municipal council of Tunbridge Wells for dealing with the slum area known as Albion-square, which consisted of 15 houses with two outside taps as their sole water supply, and had a group of water-closets in the centre of the square a few yards from the front entrances of the houses.—Mr. GREENWOOD: The answer is in the negative.

Insulin for Insured Persons.

Dr. MORRIS-JONES asked the Minister of Health the total cost of insulin supplied to insured persons for the year ending Dec. 31st, 1929; and the price per unit paid.—Mr. GREENWOOD replied: The total cost for the year was approximately £16,000. The price per 100 units was approximately 2s. 2d. during the first five, and 1s. 8d. during the last seven months of the year.

Slum Clearance in Greenwich.

Mr. PALMER asked the Minister of Health if he could state the slum-clearance areas of Greenwich selected by the local authority.—Mr. GREENWOOD replied: So far as I am aware five areas have been made the subject of representations by the medical officer of health of this borough. These are known as the Eastney-street, East-street, Charlton, Dean-street, Thames-street, and Watergate-street areas.

Nursery Schools.

DUCHESS OF ATHOLL asked the President of the Board of Education how many nursery schools local education authorities have asked him to approve as a result of the circular sent out by him some months ago jointly with the Minister of Health.—Sir CHARLES TRIEVELYAN replied: There are at present 37 proposals for new nursery schools before the Board, but I cannot say how many of these are the direct result of the circular.

Fumes from Electric Power Stations.

Mr. LOVAT-FRASER asked the Minister of Transport if he had received any complaints of offensive fumes emitted from electricity generating stations in the neighbourhood of Regent's Park; and, if so, what action he proposed to take.—Mr. HERBERT MORRISON replied: Complaints with regard to the emission of fumes from the generating stations in the neighbourhood of Regent's Park have been brought to my notice, and the Electricity Commissioners have been in communication with the undertakers on the subject. The London Power Company are conducting a series of tests on a full scale plant which is now in operation in connexion with one of their chimneys. The Marylebone Council have appointed a committee of experts to advise them in the matter. I do not think any further action on my part is called for at the present time.

Vaccination and Small-pox.

Mr. FREEMAN asked the Minister of Health the number of children compulsorily vaccinated in 1929; the number for whom exemption was claimed, the number of deaths of children from small-pox, and the number of deaths of children

Carshalton, Queen Mary's Hospital for Children.—Jun. Asst. M.O. £500.
 Central London, Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Res. H.S. At rate of £75.
 Charing Cross Hospital, W.C.—Physician for Mental Disorders, Connaught Hospital, Orford-road, E.—Sen. Res. H.S. At rate of £150. Jun. Res. H.S. At rate of £100.
 Cornwall County Council.—Locum Tenens, Tuberculosis Officer. £50
 Durham County Hospital.—Jun. H.S. At rate of £120.
 Evelina Hospital for Children, Southwark, S.E.—H.S. At rate of £150.
 Exeter, Royal Devon and Exeter Hospital.—H.S. to Spec. Depts. At rate of £150.
 Gloucestershire Royal Infirmary.—2nd H.S. At rate of £100.
 Great Yarmouth General Hospital.—Jun. H.S. £125.
 Halifax Royal Infirmary.—First H.S. Also Third H.S. At rate of £175 and £100 respectively.
 Hastings, Royal East Sussex Hospital.—Jun. Res. M.O. At rate of £100.
 Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O., also H.P. At rate of £150 and £100 respectively.
 Hospital for Sick Children, Gl. Ormond-street, W.C.—Res. M.O. for Country Branch Hospital, Tadworth. At rate of £250.
 Hospital of St. John and St. Elizabeth, 60, Grove End-road.—Res. H.P. At rate of £100.
 Huddersfield County Borough.—M.O.H. &c. £1100.
 Hull Royal Infirmary.—H.S. to Spec. Depts. At rate of £150.
 Infants Hospital, Vincent-square, Westminster.—H.P. At rate of £75.
 Inverness, Northern Infirmary.—H.P. £100.
 Lancaster Royal Infirmary.—Part-time Radiologist.
 Leamington Spa, Warneford General Hospital.—Hon. Ophth. Surgeon.
 Leicester Royal Infirmary.—Hon. Surgeon.
 Manchester Royal Infirmary.—Asst. M.O. for Massage and Electrical Dept. £100.
 Middlesex Hospital and Medical School, W.—Med. Registrarship. At rate of £300.
 Montrose Royal Asylum.—Asst. M.O. £325.
 Newcastle-on-Tyne.—Hon. Surg. to Gynecological Dept.
 Prince of Wales's General Hospital, Tottenham, N.—Hon. Asst. P. Also Hon. Surg. Reg. £100.
 Queen's Hospital for Children, Hackney-road, E.—H.S. At rate of £100. H.P. At rate of £100. Also Cas. O. At rate of £100.
 Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.S. At rate of £100.
 St. Thomas's Hospital.—Asst. M.O. in Physico-therapeutic Dept. £250. Also Sen. M.O. in Venerical Dept. £675.
 Salford Royal Hospital.—H.P., also Cas. H.S. Each at rate of £125.
 Sheffield Royal Hospital.—Res. Ophth. H.S., also Res. Anæsthetist. Each at rate of £80.
 Sheffield Royal Infirmary.—Asst. Cas. O. At rate of £80.
 Southampton, Royal South Haits and Southampton Hospital.—Cas. O. At rate of £160.
 Stafford County Mental Hospital.—2nd Asst. M.O. £600.
 University College Hospital Medical School, W.C.—Chair of Bacteriology. £1200.
 Wakefield, Clayton Hospital.—Two H.S.'s. Each at rate of £150.
 Wigan, Royal Albert Edward Infirmary and Dispensary.—Surgeon in charge of Orthopedic Dept.
 Wolverhampton Royal Hospital.—Hon. Asst. Surgeon.
 Worcestershire County Council.—Asst. County M.O. £600.
 York, Bootham Park.—Jun. Asst. M.O. £300.

Births, Marriages, and Deaths.

BIRTHS.

CHURCHER.—On April 8th, at Grange-gardens, Eastbourne, the wife of D. G. Churcher, M.D., F.R.C.S., of a daughter.
 EDWARDS.—On April 14th, at St. John's Hill, Shrewsbury, the wife of Frank H. Edwards, F.R.C.S.E., of a son.
 HUGHES.—On April 10th, at The Mall, East Sheen, S.W., the wife of Royston Hughes, L.D.S.R.C.S. Eng., of a daughter.

MARRIAGES.

DUTHIE—ALLEN.—On April 10th, at St. Peter's Church, Hale, Ogilvie Maxwell Duthie, M.D., to Mary Barbara, youngest daughter of Mr. and Mrs. E. Wagstaffe Allen, of Hale, Chester, and Glossop, Derbyshire.
 HARDWICK—JAMES.—On April 2nd, at St. Mewan Church, Cornwall, A. G. P. Hardwick, M.R.C.S., L.R.C.P., M.C., of Island House, Newquay, Cornwall, to Suzanne Clemens James, younger daughter of Mr. and Mrs. R. James, Nakajanka, Newquay, Cornwall.

DEATHS.

CAZALY.—On April 16th, at Earl Soham, Suffolk, Lieut.-Colonel W. H. Cazaly (I.M.S. retired), in his 57th year.
 GEORGE.—On April 12th, after a brief illness, W. Stanley George, M.D., of Finchley-road, Hampstead, N.W.
 GOVAN.—On April 7th, suddenly, of pneumonia, Robert Govan, M.D., D.P.H.
 HUTTON.—On April 7th, Malcolm Hutton, M.A., B.Sc., M.B., Ch.B., D.P.H., late of Shaw, Oldham, and Barrowden, Stamford, aged 49.
 SMELT.—On April 7th, at the Royal Sussex County Hospital, Brighton, Charles Allen Casterton Smelt, M.B., C.M. Edin., of Cambridge-road, Hove, aged 66.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

CORPULENCE.*

ITS CAUSES AND CURE.

By WILLIAM F. CHRISTIE, M.D. EDIN.

Prof. Stanley Eddington has shown that man is precisely half way in size between the atom and the star; obviously he allows a considerable latitude for personal expansion on either side. If, therefore, some folk are plumper than others I am not prepared to be too dogmatic about them. Yet I believe that each of us has his own ideal figure, the weight at which he feels healthiest, fittest, and happiest. Most men of 25 years of age and women of 20 are physically at their best, and no great increase of weight after these ages seems necessary or advisable. A deviation above 15 per cent. is abnormal, and there adiposity begins.

It is customary to divide cases into two main groups: 1. Those which are caused by exogenous factors; the simple or lesser adiposities. 2. Those which owe their origin to endogenous defects: the complex or greater adiposities. There is probably an intermediate group which includes a number of ill-defined borderline cases whose fatness appears to arise from both exogenous and endogenous causes. In the future, perhaps, this group will be expanded, for we are beginning to suspect that both processes operate in every case to a varying degree.

EXOGENOUS CORPULENCE.

This is by far the larger group. Here fat accumulates on an otherwise healthy person because the intake of energy in the form of food has exceeded the output of heat and work. Physiological equilibrium has been upset.

Nature has arranged that "appetite" shall dictate the amount of fuel which is required for a man's daily activity, but she also provides an internal contrivance for neutralising minor errors of judgment. It is probable that the endocrine glands play an important part in this automatic self-regulating device, but what exactly is its constitution is unknown. It cannot deal with any major errors of judgment, or even minor ones if these are long continued, but its power and strength varies to some extent with race, family, and individual. When physiological equilibrium is disturbed beyond the ability of this mechanism to rectify it, then the excess of food is tucked away within the fat depôts of the body. Thus Nature has granted to human beings a very considerable degree of personal control over their adipose tissues, and that is very necessary.

Racial adiposity.—With those groups of men whose food supply is intermittent, reserves of fat are accumulated on the body during times of plenty to live upon during periods of poverty; some tribes of North America and Central Africa swing annually from the extremes of corpulency to excessive leanness. In the Antarctic a thick layer of adipose tissue is necessary to keep out the cold; and the Eskimo develops it. There are nations that cultivate the fat figure because they like it; for instance, the chances of marriage for the thin Tunisian girl are few. Hindu moneylenders fatten on purpose because a corpulent exterior advertises their riches and their ability to lend. Most European people can become fatter if they want to. Big game hunters tell one that they fatten in the towns before proceeding into the jungle. Uncle Sam, once lean and gaunt, no longer typifies the American citizen who has assumed, as the result of prosperity, more John Bull-like proportions. The reverse process is just as attainable. The corpulent German of pre-war days had disappeared by 1918. I know of no nation that is fat willy-nilly. Perhaps the Jews are cited most frequently as the stoutest race in the world; but then their food is probably the most fat-forming of any.

Familial adiposity.—When we turn from the family of nations to the smaller family of individuals, we note again the inheritance of fat-forming habits. Fat parents develop fat children because they overfeed and under-exercise them as they did themselves. Of course, many families are marked by a common stamp, some being tall, some lean, some better covered, but these are normal conditions, whereas corpulence is abnormal. Dr. Veeder made the interesting observation about a group of fat school-boys that, in every instance, one or both parents were overweight. He studied the home conditions and formed the personal impression that an inherited tendency to corpulency existed. It may be that, if a surfeit of food is indulged by successive generations, the offspring will ultimately inherit

* Being the opening paper at a discussion on Corpulence held by the Harveian Society of London.

weak endocrine glands. Nevertheless, no one has proved it. In my last series of 75 cases of adiposity, 28 per cent. were members of families which ran to fat and frankly blamed their pedigree. They showed no evidence, however, of a sluggish metabolism, and the majority reduced themselves to normal proportions by dieting.

Corpulence appears to be an acquired disease, and chiefly the knowledge of how to acquire it is likely to be propagated from parent to child.

INDIVIDUAL ADIPOSITY.

It is instructive to consider first the occurrence of corpulence amongst those who have no voluntary powers of self-indulgence. The infant-in-arms must needs accept the fare which is provided; he cannot counteract excesses of food by voluntary increase of physical activity.

1. Infantile Adiposity.

Breast-fed babies.—Occasionally Nature makes a blunder in regard to the quantity as well as the quality of the mother's milk, and unduly fat babies result. Some women have enough milk to feed two children. It is a common fault for mothers to present both breasts to the infant at each meal, or one breast to him whenever he cries, and the child obtains more milk than he actually requires. Sudden over-feeding results in vomiting and diarrhoea; it is the long-continued slight excesses which produce in time the fat child—every day a little more than the infant needs. Too much fat in a mother's milk, although uncommon, accounts for a few plump infants.

Bottle-fed babies.—This type used to be commoner than it is to-day and arose from an excessive allowance of starch and sugar in certain proprietary foods or to adding too much lactose to cow's milk. Children, fattened on the breast or bottle, become slender after their introduction to a mixed diet, but not all escape from the after-consequences. A well-balanced diet of moderate quantity and correct proportions is necessary if the infantile automaton is to preserve the natural proportions. Comparatively slight errors of diet soon productive of adiposity. The stout hypothyroid child must be distinguished, of course, from the dietetically fat infant. The former belongs to the endogenous group of obesities.

2. Juvenile Adiposity.

The growing child, like other animals of tender age, the calf, the lamb, or the puppy, is rarely fat. On the contrary, leanness is typical of the intervening years from infancy to maturity. The maintenance diet of the average school-boy should exceed that of the average adult on account of the claims of growth—3500 calories per day compared with 2600. Growth insists on an abundance of exercise to stimulate the development of bone and muscle, and children who do not jump do not grow.

Nevertheless, corpulence does sometimes occur and is most frequent around the age of puberty. Roughly, 3 per cent. of boys become stouter at that time and a slightly larger percentage of girls. About half of them belong to the endogenous group who show signs of a pituitary or thyro-pituitary defect, but the others are corpulent without obvious cause. Possibly these have stopped growing temporarily or reduced the rate, as frequently happens. We know that they lose their excess of fat as they grow up without having altered their daily habits and without any treatment.

Some observers are not satisfied with this explanation. Since the onset of the malady coincides with the development of the sexual functions, they are inclined to blame a temporary disturbance of the glands of internal secretion, although there may be no signs of it. They would place the corpulence of puberty in the "intermediate group" of fat people who owe their over-fatness to the dual cause. Thus, consider the case of girls. The advent of ovarian secretion might be supposed to cause an under-activity of the thyroid and posterior part of the pituitary glands, and possibly an alteration in secretory activity. As the glands settle down once more and the board of endocrine control works again in harmony, the obesity disappears. The theory seems probable enough, but we must not forget that the tomboy develops at this time an unusual sedentarism, the same alimentation is continued, while the increased warmth of home life is more sought after than the old rough and tumble of open-air exercise. Girls at puberty are awakening to the maternal instinct which centres around hearth and home.

3. Adult Adiposity.

When the adult stage is reached, growth ceases and with it that perpetual motion which characterises the growing child; food should be reduced in consequence, but three additional factors must be considered—namely, occupation, temperament, and possibly climate.

Occupation.—The civilised life to-day is a very unnatural one. The whole method of earning one's living has changed

of recent years. This is an age of intensive industry, but it is mechanised up to a point. The fireman of the modern ship feeds his furnace by turning on the tap of an oil spray, whereas his predecessor had to feed his boilers by shovelling in the coal. Labour in many factories is merely the controlling of an automatic instrument. Lifts exist in hotels, houses, and offices to save muscular exertion. Brains have replaced brawn, but intellectual activity does not burn calories. Millions of workers earn their bread by scribbling from an office stool, taking physical exercise more or less desultorily during the week-ends only. Occupation must be granted a large say in the production of corpulence.

Temperament.—The phlegmatic restful person spares muscular movements while those who constantly make small ones expend a great deal of energy in the course of the day. The economy of physical effort practised by the stout is apparent to all.

Climatic conditions.—In the English summer most people lose weight; in the winter they gain it. Perhaps this is due to Nature accommodating the body to external conditions, but more likely the warmth of the climate during the colder months helps increase of flesh, while the exuberance of outdoor exercise in the warm ones tends to loss of it. In the tropics most Britishers become thinner.

The quantity of the fuel foodstuffs which an adult requires fluctuates from day to day in accordance with his activity and the coldness of the weather. No person can say that another overeats unless he knows the amount of physical work which that one has to perform. The physician in medical practice needs about 2200 calories of fuel per day while the athlete requires 4000; half of the meat of the one would be surplus to the other's requirements. You will see, therefore, how deep must be the inquiry into the habits of the corpulent before the cause can be determined. Now the exogenous adiposities of to-day are seldom the result of "open" self-indulgence. We eat less, probably, than did our forefathers, although there may still be a few people who think of Heaven as a place with a canteen in it. The gourmand enjoys that sense of repletion which comes from a distended stomach. The majority of our stout patients are gourmets in that they indulge the flavour of certain fat-forming foods. Some are carbohydrate eaters from preference (potatoes, bread, cakes, whisky). Others are attracted to fats only (butter, animal fats, cream, cheeses, oils), while the tooth of a third may be "sweet." This would not matter if they kept the total caloric value of the day's rations reasonably close to their caloric expenditure. But they do not.

When Men and Women get Fat.

Men.—There are two periods in men's lives when they tend to corpulence. 1. After giving up the athletic life to enter business, perhaps to marry and start a home of their own. 2. After attaining worldly prosperity, when they begin to ease off. These are times when activity wanes and appetites should decrease. Remember that Nature is counting calories even though men may have forgotten to do so. This is particularly true in regard to the use of alcohol. Not every man realises that a whisky and soda contains considerable fat-forming potentialities; a small whisky has the energy equivalent of one egg. Few men would care to scold four eggs after a good dinner, but quite a number will drink four whiskies. Alcoholic drinks, according to the number consumed, ought to be regarded as part of a meal and should be additional to it. For this reason quite a number of cases of obesity are alcoholic in origin.

Women.—There are three occasions in particular when women become stout: 1. Immediately after growth has stopped. Youthful maidens suffer from adiposity four times more frequently than young men of similar age. Various explanations have been offered. One has regard to the anabolic proclivities of the female and the katabolic tendencies of the male. 2. After child-bearing. About 10 per cent. of obese females date their corpulence to motherhood. Starved of sex and athletic pursuits on account of caring and nursing the baby, young mothers are encouraged to eat to excess of specially selected, highly nutritive foods, to drink Burgundy and other wines to which they were never accustomed, in order—so it is imagined—to maintain their strength and the better to suckle their infants. Most mothers reduce their figures later on by dieting, but some do not try. Successive pregnancies add to the embonpoint. Physicians should guard against over-feeding their patients whether they be convalescent from surgical operation, sickness, or maternity. 3. At the menopause. The physiological decline of the ovaries or menopausal removal would seem to justify the placing of the menopausal adiposity in the intermediate group. But all castrates do not fatten. One finds, however, that some of these cases have a basal metabolic rate on the low side, suggesting a thyroid insufficiency, although few fall so low as minus 15 per cent. It seems to me that a woman who

diet taking 12 g. of ammonium chloride a day, Aub⁸ found that the urinary calcium was increased in three days from 0.1 to 1.1 g., while the faecal calcium remained essentially unchanged. The degree of response varied with the individual, but there was always an increased calcium output.

The effects of the parathyroid and thyroid hormones on calcium excretion will be discussed later.

Calcium Content of Blood.

Very wide variations are found in the figures given for the calcium content of whole blood, serum, plasma, and corpuscles. To no small extent this is due to untrustworthy methods. The evidence is almost conclusive that the red cells of the blood contain no calcium: at the most, but minute traces can be present. Most workers state that the calcium content of the plasma is practically identical with that of the serum. There is evidence,¹⁰ however, that in true plasma, obtained by rapid cooling and centrifuging of the blood drawn under paraffin, the concentration of calcium is 10 to 15 per cent. higher than in the corresponding serum.

In estimating the blood-serum calcium, the Kramer-Tisdall method as modified by Clark and Collip¹¹ gives results with an average error of 2 per cent. and a maximum error of 5 per cent. The normal figure by this method varies between 9.0 and 11.0 mg. per 100 c.cm.

Now in the cerebro-spinal fluid the figure is only 5 to 6 mg. per 100 c.cm., and in agreement with this difference it has been found that serum and plasma calcium is but little more than half diffusible. It is obvious, therefore, that calcium is present in blood plasma in more than one form. Actually it is believed to be present in three forms:—

- | | |
|--|-----------------|
| 1. Un-ionised, non-diffusible organic compounds | { about 4.5 mg. |
| 2. Un-ionised, diffusible, or dialysable inorganic compounds | { per 100 c.cm. |
| 3. Calcium ions, diffusible | { about 3.5 mg. |
| | { per 100 c.cm. |
| | { about 2.0 mg. |
| | { per 100 c.cm. |

Electrometric determinations are responsible for the last figure, and the methods for the determination of the diffusible calcium are very unsatisfactory.

The methods of dialysing the serum against distilled water or a solution of known calcium concentration are slow and inaccurate. In collodion filtration the results may be affected by the time of filtration and by the pressure employed. For these reasons we have been content in our investigations to estimate only the total serum calcium.

Certain physiological variations in the serum calcium are of interest. Thus it has been found to be higher during the first few days of life and during the suckling period than in adult life. The claim that the serum calcium rises before menstruation and then rapidly falls is based on the faulty methods of twenty years ago, and modern work fails to confirm the observation. The best attested alteration in the serum calcium occurs during pregnancy and is doubtless due to the drain on the maternal tissues to meet the growing demands of the foetus. Bogert and Plass¹² found that the average calcium content of the serum was 9.1 mg. per 100 c.cm. for 23 women at the time of labour, and 10.2 mg. for 12 normal non-pregnant women.

It has been shown that the blood calcium of certain birds increases very considerably at the period of ovulation. Thus in female pigeons¹³ a rise in blood calcium begins 123 hours before the beginning of the formation of an egg-shell. Subsequently, during a period of from three to five days these birds withstand without trace of adverse effect a hypercalcaemia up to 20 mg. per 100 c.cm. Similarly the female cod¹⁴ in the spawning season has a blood calcium varying from 12.7 to 29 mg. per 100 c.cm., whereas the corresponding figure in the male lies between 9 and 10.5 mg. This calcium is probably required for the calcification of the eggs, which are especially rich in calcium content.

Calcium in Tissues.

Speaking approximately, for there are no reliable figures, calcium is distributed evenly throughout the soft tissues in amounts comparable to those found in the blood plasma. Thus muscle contains 0.5 mg. per 100 g. When, however, we come to the skeleton the corresponding figure is about 10,000 mg. Calcium phosphate constitutes 80 per cent. of the mineral content of bone. There are in addition calcium carbonate, which makes for greater hardness, magnesium phosphate, and traces of fluoride, the last being present in greatest amount in the enamel of teeth. The protective shells of invertebrates consist almost entirely of calcium carbonate, but traces of phosphate are invariably present, and there is good ground for belief that the presence of phosphate is absolutely essential both for shell and for bone formation.

The calcium in milk is about equally divided between organic and inorganic constituents, the organic compound, calcium caseinogenate, being non-diffusible. The inorganic calcium is chiefly calcium hydrogen phosphate, with some bicarbonate, and citrate. The activity of the mammary gland is responsible for a concentration of calcium which averages 42 mg. per 100 c.cm. in human milk and 120 mg. in cow's milk.

Functions of Calcium.

The most obvious function of calcium in the body is, of course, the formation of bone. It has perhaps been insufficiently emphasised that the skeleton of the mammal is not only a supporting structure, but is also a reservoir of calcium and phosphorus. Even after full growth is complete, bone salts are being continuously removed and renewed, and they are not once and for all laid down and fixed. And since bone is the only considerable reservoir of calcium in the mammal, the skeleton can be drawn upon not only for the skeletal needs of the foetus where there is a dietary deficiency of calcium, but, apparently often as a normal procedure, as in the production of milk. The hen, on a diet deficient in calcium, can draw on its skeleton for the calcium of the egg-shell. Further, the skeleton is not the only structure which acts as a reservoir for calcium. There is experimental evidence that the shell of the egg can be dissolved by the carbonic acid produced by the growing embryo, to yield a soluble calcium salt for the needs of that embryo: 80 per cent. or more of its calcium requirements are provided from the shell.¹⁵

Apart from the growth and maintenance of the skeleton, calcium plays an important part in the blood and tissues by maintaining along with other ions a balanced system which determines the degree of irritability of muscle and nerve. In this way calcium ions help to control the heart beat, the contractility of plain and striped muscle, and the transference of impulses at the neuro-muscular junctions and through synapses. In general it may be stated that calcium ions play an important part in lessening the irritability of the tissues containing them.

Nevertheless wide variations from the normal can exist without apparent interference with such functions. Thus in post-operative tetany and infantile tetany the serum calcium may drop to 6 mg. per 100 c.cm. before any symptoms or signs of lack of calcium are observed. Conversely, in parathyroid over-dosage and in spontaneous hyper-parathyroidism we have observed symptomless hypercalcaemia, the serum calcium values being 19.8 and 16.7 mg. per 100 c.cm. respectively.

An important function of calcium is to aid in the coagulation of shed blood. Mellanby¹⁶ showed that the action of calcium is specific, since, although salts of magnesium, strontium, and barium will, in the presence of thrombokinase, convert prothrombin into thrombin, none of them compares in potency with calcium. It follows that any manipulation which depletes the blood of calcium ions, such as the addition of oxalate or citrate, prevents clotting. The delayed coagulation time in hæmophilia may be due,

theoretically, to a variation of any one of the factors concerned in clotting, but there is no evidence worth the name to indicate a calcium defect.

Cases of fatal hæmorrhage after operations for obstructive jaundice may perhaps be explained by removal of calcium ions which have combined with bile salts. Little or no satisfactory work is to be found on this subject.

In the clotting of milk, calcium ions are essential in the process of converting casein into insoluble calcium caseinate, the clot mesh.

NORMAL METABOLISM OF PHOSPHORUS.

Phosphorus is ingested in the food as nucleoprotein (meat), phosphoprotein (milk), lecithin (egg yolk, liver), and as inorganic phosphate. It is found in the blood, not only in the inorganic state, but also in combination with a variety of organic radicles. The organic compounds are acid-soluble "ester phosphorus," and alcohol-ether soluble "lipin phosphorus." It is, perhaps, not sufficiently realised that less than one-twelfth of the total phosphorus is present as inorganic phosphate.

Plasma Inorganic Phosphorus.

The plasma and corpuscles contain equal amounts of inorganic phosphorus, so that the results of analyses may be expressed as milligrammes of phosphorus per 100 c.c.m. of whole blood or plasma. Most of the early work on blood phosphate must be accepted with caution, for it was not known before 1914 that the distribution of phosphorus changes when blood is allowed to stand. Once the corpuscles have been laked, the liberated organic esters are very rapidly hydrolysed by the plasma phosphatase, and the concentration of inorganic phosphate rises rapidly. However, with adequate precautions, using the method of Briggs,¹⁷ the experimental error should not exceed 2 per cent.

In health the level of inorganic phosphate in the blood varies between 2.5 and 3.5 mg. phosphorus per 100 c.c.m. In children, where ossification is more active, readings up to 5 mg. per 100 c.c.m. are found. The blood obtained from the umbilical cord at birth may contain as much as 6 mg. per 100 c.c.m.

The metabolism of phosphorus is closely interwoven with that of calcium, and many of the observed fluctuations in the blood phosphate can be accounted secondary to changes in calcium. There is often a reciprocal relationship between calcium and inorganic phosphorus in the blood, though this is only approximate and does not apply where absorption of phosphorus is defective.

Functions of Phosphorus.

Phosphorus compounds take part in at least four important metabolic processes. They are in some way essential to the storage or utilisation of carbohydrate, they enter into the chemical changes which precede the contraction of muscle, they are concerned with acid-base equilibrium, and they are essential to the deposition of bone.

The physico-chemical mechanism of ossification is little understood. Freudenberg and György¹⁸ have suggested that the cartilage protein forms a compound of calcium by virtue of its acidic groups, that the resulting compound, having now a preponderance of basic groups, combines with phosphate ions, and that the calcium-protein-phosphate complex so formed breaks down with deposition of insoluble calcium phosphate and liberation of the original protein. Holt, La Mer, and Chown,¹⁹ from their work on the physical chemistry of calcium phosphate solutions, conclude that the blood serum is to be regarded as a supersaturated solution of tertiary calcium phosphate, and that the plasma bathing the bone matrix, where solid calcium phosphate is present, readily gives up its surplus and so enables the bone to grow.

The interesting theory of Robison²⁰ as to the possible significance of bone phosphatase in the process of ossification has been supported by much experimental evidence. The work of Kay²¹ on

plasma phosphatase, in the study of certain metabolic diseases of bone, has provided circumstantial support for Robison's theory from an entirely different quarter.

PHOSPHATASES.

For our knowledge of the distribution and possible functions of phosphatases in the body we are indebted to Robison, Kay, and collaborators. Phosphatases are enzymes which hydrolyse phosphoric esters such as glycerophosphate and hexosephosphate. Many of these esters form soluble calcium salts. Such esters are widely distributed in the tissues, mainly inside the cells. Two such esters occur in mammalian red cells, and a phosphoric ester, hydrolysable by animal phosphatases occurs, in small quantities only, in human plasma. Phosphatases also hydrolyse pyrophosphates which are said to occur in muscle tissue.

Distribution of Phosphatases.

Phosphatases are very widely distributed in mammalian tissues. In the human adult the epithelial portion of the intestinal mucosa is richest in phosphatase, the whole kidney next. There is more in the cortex of the kidney than in the medulla, and more in the mucous membrane of the intestine than in the submucosa. Adult bone contains phosphatase very unequally distributed, the enzyme being present mainly below the periosteum. Per unit weight of bone, young growing bones contain much more phosphatase than adult bones. Again the distribution is very irregular, the enzyme being present mainly in the zone of provisional calcification and in the periosteum. Fetal bones contain a still higher proportion of phosphatase per unit weight of bone. The concentration of phosphatase in and about the cells of the ossifying zone in fetal cartilage is probably greater than that of phosphatase in any other tissue. The fetal kidney, on the other hand, contains considerably less phosphatase than the kidney a few days after birth.

Plasma Phosphatase.

In 1929 Kay published a method²² for estimating the activity of the phosphatase in the plasma. He expresses this enzyme activity in terms of the number of milligrammes of phosphorus liberated as inorganic phosphate from excess of sodium β -glycerophosphate in 48 hours at 38° C. and at pH 7.6 by 1 c.c.m. of plasma. Under these conditions the average value for normal plasma is 0.15 mg. In young infants the figure is higher.

In certain generalised diseases of bone the phosphatase of the plasma frequently rises to 10 or 20 times the normal. Very high figures are constant in osteitis deformans. In generalised osteitis fibrosa (three cases), in secondary carcinomatosis of bones (one case), in rickets and in renal rickets high figures have been found. On the other hand, in focal osteitis fibrosa (eight cases) and in osteogenesis imperfecta the figures are normal.

Bone Phosphatase.

There seems little doubt that phosphatase plays a part in the chain of events by which the deposition of calcium phosphate in growing bones is brought about. Robison's hypothesis²⁰ may be briefly stated as follows: the osteoblasts and hypertrophic cartilage cells secrete a very active phosphatase, which, by hydrolysing the phosphoric esters of the blood, brings about a local increase in the concentration of phosphate ions. The solubility product of tertiary calcium phosphate is thereby exceeded, and deposition of this salt occurs in the ossifying zone. The enzyme probably plays a part also in the maintenance and repair of bone in the adult.

The evidence in favour of this hypothesis may be briefly outlined as follows:—

1. Phosphatase is present in the growing bone in greatest amount in those areas in which deposition of calcium phosphate is proceeding most rapidly.
2. It can be demonstrated *in vitro* that a growing bone split longitudinally is still capable of the deposition of calcium phosphate from a solution of a

soluble calcium phosphoric ester salt such as calcium hexosemonophosphate or calcium glycerophosphate, and that deposition occurs mainly in the cells in the zone of provisional calcification.

3. Phosphatase appears in cartilage simultaneously with the appearance of centres of ossification.

4. There is no phosphatase in cartilage which is not ossifying.

5. There is a substrate for the enzyme present in red cells and also in circulating plasma.

6. In certain generalised diseases of bone the plasma phosphatase is high. This establishes another correlation between phosphatase and bone tissue, though its exact significance has still to be discovered.

Phosphatases in Intestinal Mucosa and Kidney.

Phosphatases in the intestinal mucosa hydrolyse the phosphoric esters in the food. All the evidence at present available indicates that phosphoric esters taken by mouth are absorbed as inorganic phosphates. Any phosphoric ester in the food is probably completely hydrolysed by the phosphatases of the intestinal juice and the mucosa before absorption into the blood stream. The rate of hydrolysis of various phosphoric esters is not, however, the same, so that the more resistant will probably be hydrolysed further down the intestine than the less resistant. Milk, for example, in addition to caseinogen, contains calcium phosphate in at least seven other forms of combination. These compounds of milk will be hydrolysed and their components absorbed at different levels in the intestinal tract. The peculiar ease with which the calcium and phosphorus of milk are taken up from the intestine is probably dependent upon these facts.

The kidney phosphatase possibly plays some part in the secretion of inorganic phosphate in the urine.

METHODS OF THE METABOLISM WARD.

In the study of calcium metabolism it is necessary to know, not only the levels of calcium and phosphorus in the blood, but also the calcium and phosphorus balance; for just as the level of a river does not indicate the direction in which it flows, so the levels of the figures in the blood give us, in themselves, no indication as to whether calcium is flowing into excretory channels or into the tissues.

In our studies of endogenous calcium metabolism^{22, 23} we have given a diet containing only 100 mg. of calcium a day but adequate in all other respects. This is necessary in order to reduce to a minimum the amount of unabsorbed calcium in the faeces. Fluid and sodium chloride intake have been kept constant, and distilled water has been used in the preparation of all food and drinks. Sufficient alkali has been given by mouth to make the reaction of the 24-hour mixed urine neutral to phenol-sulphone-phthalein (pH 7.3). The faeces have been divided into three-day periods by the oral administration of 0.3 g. of carmine alum lake every third day. The urine has been obtained in 24-hour specimens.

Since inorganic salt excretion reaches a constant level only very slowly, we have endeavoured to change our conditions of study not more than once in twelve days.

EFFECTS OF THE PARATHYROID HORMONE.

The parathyroid glands exert a specific effect upon calcium metabolism. The pioneer work of MacCallum and Voegtlin²⁴ demonstrating a reduction of serum calcium in dogs after parathyroidectomy has been abundantly confirmed. It is well established that this condition is relieved by the administration of calcium salts. The idea that it is due to guanidine intoxication remains unsupported by adequate evidence.

Effects of Parathyroid Extract on the Blood.

The view that calcium deficiency is the direct cause of post-operative tetany is considerably strengthened by the work of Hanson²⁵ and Collip,²⁷ who isolated an active extract of the parathyroid gland. Injections of this substance abolish tetany in parathyroid-

ectomised dogs, the serum calcium being restored to normal.

I will illustrate this from some of our unpublished experiments.²⁸

Control of Tetany after Total Thyro-parathyroidectomy in a Dog.—A dog weighing 6.5 kg. had been kept for four weeks on a meat diet. Total thyro-parathyroidectomy was performed under ether anaesthesia. Violent tetany, with extensor spasms of the limbs, appeared 10 hours after operation. The dog was found lying on its side very ill, with great muscular weakness and vomiting. There was striking hyperpnea with a respiratory rate of 135 per minute, and laryngeal stridor with a hoarse bark. The serum calcium was 5 mg. per 100 c.cm. and the inorganic phosphorus 6.5 mg. per 100 c.cm.

An intramuscular injection of 15 units of parathormone²⁹ was given, and three hours later the dog was normal. There was no muscular weakness. Normal activity and appetite had returned. The respiratory rate and bark were normal. The serum calcium had been raised. However, unless injections of the hormone were given daily, the serum calcium fell and the dog relapsed into violent tetany.

Administration of Collip's extract to normal dogs raises the serum calcium above normal to an extent so nearly proportional to the dose as to afford a means of standardisation.

During certain observations on patients suffering from chronic lead poisoning²² we had the opportunity of investigating the effect of parathormone on the chemistry of the blood and on calcium excretion. These patients were kept on a constant diet containing an inadequate amount of calcium. Parathormone was given by intramuscular injection either twice or three times a day. In regulating the dosage we were guided very largely by the level of the blood calcium. In five patients out of six we found that, by giving an average dose of 55 units daily, the blood calcium could be increased to 13 mg. per 100 c.cm. or more within eight or nine days. The most effective method was to give three doses a day and to increase the daily dosage continuously from, say, 20 to 100 units by adding 10 units daily (Fig. 1). This gradual elevation of the calcium level in the blood is the most dramatic effect of parathormone, but its extent varies in different individuals, and we found that it was more marked when calcium lactate was added to the diet.

Effects of Parathyroid Extract on Calcium Excretion.

Our observations on patients suffering from lead poisoning enabled us to contribute to the vexed question of the relation of the parathyroid glands to calcium excretion. Now, before the isolation of potent extracts of the parathyroids, erroneous conclusions had been arrived at as to the effect of thyro-parathyroidectomy on calcium excretion. Thus the statement of MacCallum and Voegtlin²⁴ that after this operation dogs showed an increased excretion of calcium has not been corroborated. Cooke²² repeated their work and was unable to find any change in the excretion of calcium after parathyroidectomy. In spite of this contradictory report, the statement of MacCallum and Voegtlin became widely accepted. Thus arose the idea, to which Salvesen²⁹ later contributed, that parathyroidectomy was associated with a lowered threshold for the excretion of calcium by the intestines. It was supposed that the resulting drain on calcium kept the blood-serum calcium at a low level. Greenwald and Gross³⁰ have demonstrated that the true conception of the relation of the parathyroid glands to calcium excretion is the very reverse of that above stated. By a technique which eliminated many sources of error incurred in previous animal experiments, they demonstrated that dogs after parathyroidectomy actually showed a decrease in the excretion of calcium. In a later series of experiments³⁰ they were enabled, by the use of Collip's parathyroid extract, to approach the problem from the opposite point of view. They injected normal dogs with the extract

* Throughout our experiments we have used this preparation of Collip's parathyroid extract generously supplied to us by the courtesy of Eli Lilly and Company, of Indianapolis.

and found that the increased concentration of calcium brought about in the blood-serum was followed by an increase in the excretion of calcium.

During our investigations on patients with chronic lead poisoning we were able to make nine observations on the effects of parathormone on calcium excretion when the intake was known. It will be seen from Fig. 1 that, in such a patient, during control periods on a low calcium diet a negative calcium balance already existed, the average excess of output over intake being 0.37 g. in a three-day period. In all our observations parathormone definitely increased this negative calcium balance, the average increase being 53 per cent. The increase was roughly proportional to the dosage given. Thus, where parathormone was given in increasing doses for 16 days (Fig. 1) the negative calcium balance rose to a maximum of 1.01 g. in a three-day period, a figure very much higher than the average quoted above. When parathormone was discontinued, the calcium output did not immediately drop to normal but remained somewhat raised for periods of from three to six days.

The increase of calcium output was very much more marked in the urine, the increase of faecal excretion being negligible. Where large doses of parathormone were given, the urinary output of calcium rose to very high figures. Thus in the case referred to above, where parathormone was given in increasing doses for 16 days, the output of calcium in the urine rose from 0.089 g. to 0.751 g. in a three-day period.

The relation between the level of the blood calcium and the calcium excretion is important. Although we found that hypercalcemia was always associated with an increased calcium output, the converse was not found to be true. In one case large doses of parathormone failed to produce a significant rise in the blood calcium, but, in spite of this, the total calcium excretion was doubled.

In considering the physiological action of the parathyroids, the source of these large amounts of calcium appearing in the urine is of fundamental importance. We consider it justifiable to infer from our results, as Greenwald¹⁰ did from his animal experiments, that parathormone, administered during a deficient calcium intake, causes increased excretion of calcium salts from the bones. This will be referred to later in connexion with hyper-parathyroidism and also in dealing with the question of the storage of lead, mercury, and radium in the bones.

Effects of Parathyroid Extract on Phosphorus Metabolism.

Though the most dramatic effects of parathormone are on the blood calcium and calcium excretion, there is evidence¹¹ that its primary effect is on phosphorus excretion. Parathormone abruptly increases the urinary phosphorus excretion without affecting the faecal excretion. At the same time the level of the inorganic phosphorus in the blood is reduced. When parathormone injections are stopped, the urinary phosphorus excretion rapidly falls to a level below that found before. These changes are more rapid than those just described in the case of calcium metabolism. They are also greater than can be explained by a theoretical calculation of the phosphorus liberated with calcium and nitrogen (from calcium phosphate and protein respectively), so that the excreted phosphorus is evidently derived partly from the body fluids.¹²

These remarks apply only to the primary effect of parathormone on phosphorus metabolism. If parathormone is continued in large doses a secondary effect appears later. It was first emphasised by Collip that when a certain critical level of serum calcium has been reached, following parathormone injections, the blood phosphorus rises abruptly. This may be due to an alteration in kidney function resulting from the high serum calcium, for the non-protein nitrogen of the blood also rises. Thus a later effect of parathormone on phosphorus meta-

bolism is brought about, which is exactly opposite to the primary effect.

There are several other observations which lend support to the view that the primary action of parathormone is on phosphorus. Greenwald¹⁰ has shown that there is a marked retention of phosphorus in the first two days after parathyroidectomy. This suggests the possibility that the bad effect of a meat diet on parathyroid tetany may be due to its high phosphorus content. Collip¹³ showed that, following

FIG. 1.

Effect of parathyroid extract on the blood calcium and on the calcium excretion.

The interval marks on the abscissa represent five days.

In the upper portion of the chart the upper block represents treatment with parathyroid, the adjacent scale indicating units per day. The lower blocks represent the calcium intake in three-day periods. The faint line represents the excretion of calcium in the urine expressed in output for three days. The heavy line is the total excretion of calcium for urine and faeces for three-day periods. The distance between heavy line and blocks therefore represents the positive or negative calcium balance.

In the lower portion of the chart is shown the blood-plasma calcium.

parathyroidectomy in the rabbit, the serum phosphorus rose without much change in the serum calcium, and that parathormone, if administered directly following operation, would prevent this rise. He stated that "these observations tend to emphasise the importance of phosphorus in relation to the pathogenesis of tetany." Further, tetany has been produced in dogs by intravenous injection of phosphates,¹⁴ and likewise by administering large doses of phosphates by mouth.¹⁵

Effects of Over-dosage by Parathyroid Extract.

The work of Collip on dogs¹⁶ brought to light a new entity—hypercalcemia. This condition has since been found to occur in man, both spontaneously and as the result of parathyroid over-dosage. In Collip's observations on dogs no ill-effects were noted if the dosage of parathyroid extract was only sufficient to cause a rise in the serum calcium to 14 or 15 mg. per 100 c.cm. Large doses of the hormone, however, administered five times in the 24 hours often caused death within 48 hours of the first dose. Though in such cases the blood calcium rose to 20 or 21 mg.

per 100 c.cm., Collip made no claim that the hypercalcaemia was the immediate cause of death. In describing the condition of these animals he states that "the clinical manifestations of hypercalcaemia in dogs appear to be loss of appetite, dullness, drowsiness verging on coma, general atonia, and a failing circulation. The animals are also obviously dehydrated, the blood becomes very concentrated, and it becomes a matter of great difficulty to secure serum from blood samples for analysis even when a high power centrifuge is used. Immediately after death the blood in the heart and great vessels forms a firm clot."

Complete investigations of the blood chemistry showed that the inorganic phosphorus rose in the later stages of hypercalcaemia and that there was nitrogen retention. Thus in one dog the blood at death had a phosphorus content of 13 mg. per 100 c.cm. and a urea content of 111 mg.

During our investigations²² a severe hypercalcaemia was produced inadvertently in one case by overdosage with parathormone.

CASE 1. Overdosage by Parathyroid Extract in Man.—A man of 60 years (M. G. H., Reg. No. 272916, 1925), a house painter, was being treated for lead poisoning. It will be seen from Fig. 2 that he was being given a low calcium diet to which varying doses of calcium lactate were added. Calcium lactate was given for four days before commencing the parathormone. At this point, owing to an error in the interpretation of the orders, the calcium lactate was reduced and then omitted. During the next two days the dose was increased to compensate for the previous defects. Meanwhile the parathormone had been continued in increasing doses, until on the eleventh day the level of the blood calcium had risen to 19.8 mg. per 100 c.cm. It remained at this level for 48 hours; then, although all treatment had been discontinued, it fell only very gradually to normal levels during the next three days. The first effect on the plasma phosphorus was that it dropped to 2.7 mg. per 100 c.cm., but the late effect was a rise to 6 mg. per 100 c.cm., and this occurred 24 hours after the maximum rise in calcium. The pH of the blood was not estimated. The carbon dioxide content of the venous blood was 75 volumes per cent. The total base, protein, and water-content of the serum were normal (fixed base 168 c.cm. N/10 per 100 c.cm. serum; water-content, 92.2 g., protein, 5.9 g.). The non-protein nitrogen was followed from the time the blood calcium was first found to be raised. It showed a rise to a maximum of 95 mg. per 100 c.cm., this rise occurring two days after the maximum rise in calcium. During the next week it fell gradually to within normal limits.

The changes in the physical properties of the blood observed by Collip in dogs suffering from parathyroid overdosage were absent. Throughout the whole time the patient remained up and about, and, except for slight nausea and loss of appetite, appeared to be normal.

PARATHYROID TETANY.

Parathyroid deficiency occurs in clinical medicine both as post-operative tetany, following operations

upon the thyroid, and as spontaneous hypo-parathyroidism, which is analogous to myxedema. Both conditions are rare, and metabolic studies have shown them to be of great interest.

Post-operative Tetany.

Owing to the fact that radical thyroidectomy is not a common practice in this country, post-operative tetany is rare. It is not so in all countries, especially in those where operations for endemic goitre are common. In the United States, where it is customary

to remove nine tenths of the thyroid gland for exophthalmic goitre, post-operative tetany is more often seen than it is here. It is for this reason that Lahey²³ examines as a routine the specimens removed at operation, and, if any tissue suggesting parathyroid is found, he transplants it into the sternomastoid muscle, preferably reserving a portion for histological examination.

As an instance of the severe and ultimately fatal outcome which is sometimes seen in post-operative tetany, I will refer to a

case^{27, 28} I saw in the Massachusetts General Hospital.

Aub's Case of Post-operative Tetany.—The patient was a girl who had been examined at the age of 17, having a history of a goitre, first noticed three years before. Tremor, tachycardia, and slight exophthalmos were found. The basal metabolic rate was plus 45 per cent. Later in the same year two extensive operations were performed constituting total thyroidectomy. Two months after the second operation, attacks of difficult breathing occurred and were later accompanied by severe carpal spasm and sometimes by convulsions. Two years later cataracts began to appear in both eyes, necessitating bilateral lens extraction.

On examination nine years after thyroidectomy, the skin was found to be dry and the axillary and pubic hair scanty. No thyroid tissue could be palpated in the neck. Chvostek, Trousseau, and Erb signs were positive. The blood calcium was 4.3 mg. per 100 c.cm., and the inorganic phosphorus 5.6 mg. per 100 c.cm. The basal metabolic rate was minus 18 per cent. 15 units of parathormone given daily raised the blood calcium to 8.7 mg. per 100 c.cm. in 18 days. When it reached this level the attacks of difficult breathing and tetany disappeared.

The output of calcium on a known low calcium intake was estimated during this treatment, and found to be excessively low. In fact the output was almost the same as the intake and much less than that of normal individuals on the same diet. This occurred in spite of the fact that she was being given 15 units of parathormone daily, which should have caused an increase in her calcium excretion. These figures for calcium excretion are lower than those found in any other disease and indicate that the low blood calcium is due, not to an increased permeability of the kidney or intestinal mucosa to calcium, but rather to a diminished endogenous calcium metabolism and a diminished demand upon the calcium reserves in the bones.

FIG. 2.

Effect of parathyroid over-dosage on the chemistry of the blood.

The interval marks on the abscissa represent days.

A low calcium diet was given throughout. The black areas represent calcium lactate in grammes. The scale for parathyroid represents units per day. The calcium and phosphorus were estimated in blood-plasma, the non-protein nitrogen and carbon dioxide content in venous blood.

Unfortunately, the effect of parathormone gradually diminished in this patient. Initially the blood calcium had been raised by a dose of 15 units, whereas after some months doses of 100 units had no effect at all. The results to the patient were disastrous, for the persistent low blood calcium was accompanied by severe attacks of tetany, associated with bronchial spasm, laryngeal spasm, and unconsciousness, and in such an attack she died.

Aub³ interprets this phenomenon as an "immunity" to parathyroid extract. He states that

"unfortunately, parathormone has several disadvantages, which make its long-continued clinical use unsatisfactory at present. First, its action varies markedly in different individuals. Thus, one normal individual will show a marked reaction, while another will get no effect from a similar dose of the same extract. Second, and more important, there is an immunity to the drug which has developed in many of our cases after a few weeks of treatment. When such an immunity appears, even very large doses of parathormone exert no influence on blood calcium or phosphorus. This loss of potency has lasted in one case for a full year, and is dependent upon a resistance to the preparation and not to a drainage of the storehouse of calcium, for an increased calcium excretion followed the administration of ammonium chloride after parathyroid had proved inert. This is apparently the only active principle of a gland of internal secretion which develops such an immunity, and this effect may possibly be dependent upon the protein still present in the extract."

Fortunately, chronic post-operative tetany is often a mild disease easily controlled by calcium therapy. The following case, which I have recorded elsewhere,²⁸ illustrates this.

CASE 2. Post-operative Tetany.—A single woman of 44 years (L.H., Reg. No. 40299, 1928). She was born at Wolverhampton, where goitre was endemic, and lived there until the age of 21. At the age of 18 she first noticed a swelling in the neck, which gradually produced pressure symptoms. At the age of 22 an extensive thyroidectomy was performed. Two weeks after this operation carpopedal spasm occurred. During the 22 years which followed, attacks of tetany frequently recurred, sometimes even affecting the facial, oculo-motor, laryngeal, and pharyngeal muscles.

On examination, although no thyroid tissue could be palpated in the neck, there were no signs of myxœdema. Trousseau, Chvostek, and Erb signs were positive. Visual acuity was normal, but examination with the slit-lamp showed opacities in each lens. The serum calcium was 0.8 mg. per 100 c.c.m., and the plasma inorganic phosphorus 5.1 mg. per 100 c.c.m. The basal metabolic rate was minus 5 per cent.

The rational treatment was to give a high calcium diet together with thyroid extract by mouth and parathormone by intramuscular injection. The average daily dose of parathormone was 30 units and of thyroid extract grs. 4. The patient completely lost all her symptoms as soon as the serum calcium rose to normal. After five days' treatment hypercalcaemia appeared (serum calcium 16.6 mg. per 100 c.c.m.).

Further study of this case showed that, on a high calcium diet together with 10 g. of calcium lactate daily, all symptoms and signs of latent tetany were abolished and the blood calcium and phosphorus figures were restored to normal. During the whole of 18 months only one relapse has occurred, and that was due to a failure to take the calcium lactate. At all other times she has been free from tetany, twinges, and restlessness at night. She has resumed writing letters and needlework and is now successfully employed as a housekeeper, whereas for the 22 years following the operation she had been disabled from work of any kind by stiffness of the fingers.

Spontaneous Hypo-parathyroidism.

It has now been definitely shown that just as myxœdema is, as a rule, a spontaneous hypothyroidism, so an analogous condition of the parathyroids exists. This is exactly similar to post-operative tetany, except that it is of spontaneous origin. Albright and Ellsworth⁴⁰ have recorded such a case.

Case of Spontaneous Hypo-parathyroidism (Albright and Ellsworth).—A boy of 14 was admitted to hospital for the relief of tetany. At the age of 8 attacks of laryngismus had occurred, followed the next year by carpopedal spasm. At the age of 10 Chvostek and Erb signs were positive, the blood calcium being 4.9 mg. per 100 c.c.m. and the phosphorus 10.1 mg. The boy then became worse, so that at the age of 14 he was having each day about 16 attacks of carpopedal spasm, sometimes with momentary loss of consciousness. The blood calcium was still low and the

phosphorus high. The basal metabolic rate was minus 6 per cent. Following the administration of parathormone there was complete relief. The blood calcium was raised to 16.2 mg. per 100 c.c.m. and the phosphorus dropped to 4.7 mg. However, after discontinuing the injections of parathormone, symptoms returned in one week. Seen later, at the age of 15, the boy again had tetany; the blood calcium was 5.3 mg. per 100 c.c.m., and the phosphorus 10.8 mg. The urines were normal.

Radiograms of the bones showed no abnormality. Ophthalmoscopic examination revealed a sub-capsular lenticular opacity in the right eye and a few lenticular opacities in the left.

A similar case²⁸ has been studied in a man of 52 with a history of attacks of tetany occurring over ten weeks, followed by failing vision. On examination Trousseau and Chvostek signs were found to be present. The blood calcium was 5.1 mg. per

100 c.c.m., and the phosphorus 7.3 mg. The basal metabolic rate was minus 15 per cent. Opacities were found in the lenses of both eyes.

In these two cases there are many features which strongly suggest parathyroid deficiency. The low serum calcium with high plasma phosphorus is comparable to the findings in post-operative tetany and is the exact converse of what has been found in parathyroid over-dosage and hyper-parathyroidism. The administration of parathormone relieved the tetany, raised the blood calcium, and lowered the phosphorus. Finally the occurrence of lenticular opacities is comparable to what is found in post-operative tetany.

LESIONS OF ECTODERMAL TISSUES.

Cataract, brittleness and ridging of the nails,⁴¹ loss of hair,⁴² and defects in the enamel of teeth, giving rise to several transverse ridges one above the other: all these defects in ectodermal tissues have been described in tetany. None of these changes is common, but the first is met four times as frequently as any of the other three.

The association of cataract with tetany was first recorded about 50 years ago. It has been described in endemic tetany,⁴³ post-operative tetany, rickets, and spontaneous hypo-parathyroidism.⁴⁰ In 1906 Erdheim⁴⁴ observed the occurrence of cataract in rats six months after experimental parathyroidectomy. Thyro-parathyroidectomy in dogs may produce opacities in the lens within periods varying from three months⁴⁵ to two years.⁴⁶ Reports of 38 cases of human post-operative tetany associated with cataract have been published⁴⁷ to date. Since 1924 it has been possible,⁴⁸ by means of the slit-lamp, to demonstrate opacities in the lens where no visual disturbance exists. Such opacities were found⁴⁹ in the following case (Fig. 3).

CASE 2 (continued). Post-operative Tetany.—No opacities could be seen in the lenses by ordinary focal illumination, or with the ophthalmoscope and a high plus lens, but with the slit-lamp three types of opacity were seen. Opacities of one type were flaky white in appearance, in some places aggregated together to form a plaque, and situated under

FIG. 3.

Post-operative tetany (Case 2).
Opacities in the lens, as seen with the slit lamp.

ON RADIATION THERAPY IN CANCER.

By A. T. TODD, M.B. EDIN., M.R.C.P. LOND.,
HON. ASSISTANT PHYSICIAN, BRISTOL ROYAL INFIRMARY.

THE claim of any remedy to have specific action or immediate favourable effect on a disease process has as a general rule subsequently been proved unjustified. Almost always it has been found that the action of such a remedy was mediate—acting first upon some other tissue. This finding is so frequent that it constitutes some *prima facie* evidence that radium, or radiation, does not act directly on the cancer cell.

The belief is current that radium does act specifically and primarily on the cancer cell. It is freely admitted that it also acts on the normal tissues, but this latter action is regarded as subsidiary and rather as a nuisance, inasmuch as it may make the application of radium difficult or even impossible. The action of radiation is considered to effect some alteration of the cancer cell which adversely affects mitotic division and so interferes with the continuity of its growth. The present technique of radiation therapy is based on this conception. If it were correct, then radiation treatment should be relatively simple; any group of similar cancers of the same region and of the same extent should respond in the same manner to the same dose of radiation. This, however, is not found to happen; some cases do well, others do little, and some do not respond at all—that is, in a favourable manner. In an attempt to explain this variability the conception of radio-sensitivity has been evolved. The cancers which do not respond are termed radio-resistant and the ingenuity of the histologists has been fully exercised in attempts to distinguish between the sensitive and non-sensitive cancers. One very carefully examined series showed that it was the cancers of medium virulence from the histological standpoint which were the most sensitive.¹ Another series showed that it was the more anaplastic, or more virulent, which were the most sensitive.² Yet another experiment showed that the more virulent cancer was more sensitive in the animal, but was as resistant as a very resistant cancer *in vitro*.³ If radiation did act specifically or immediately on the cancer cell, the response to radiation *in vitro* should be different from that actually found. When the living, growing cancer cell, in pure culture, with nothing to shield it, is exposed to radiation, the result should be certain and easy to attain; yet considerably more radiation is needed to kill this pure culture than is necessary to kill the same cancer in the living animal. The *in vitro* dose is always much larger than the *in vivo* dose.⁴

Some of our experiments appear to furnish evidence against the specific action of radiation on cancer.⁵ After treatment with selenide of lead—that is, after impregnation of the tissues with a compound which is ionised* by hard X rays or gamma rays⁶—the application of these rays is followed by a rapid increase in the size of the neoplasm. According to the current theory, growth should have been lessened. Mitotic division must have occurred with greater frequency than before the radiation was applied. This is found to be the case both with cancer in man and implanted cancer in mice. Further evidence against the current view appears from consideration of the regional response to radiation therapy—e.g., the differences in response to radiation of a primary carcinoma of the tongue and its metastases in the lymph glands of the neck. In this case it is the same cancer, often with no histological differences, yet in the one place the cancer is very sensitive and in the other place very resistant. These findings appear to furnish some evidence that radiation does not act primarily upon the cancer cell. The alternative is that radiation acts upon the

local and/or upon the general mesoblastic defence mechanisms.

The Stroma.

The local defence mechanism is probably the junction tissue—this is the mesoblastic defence barrier which tries, and apparently tries in vain, to limit the spread of the neoplasm. This junction tissue is not well known and its possible significance has not been appreciated. It consists of lymphocytes, plasma cells, monocytes and macrophages, various phases of fibroblasts, eosinophil and basophil leucocytes, and the blood and lymph channels. The relative predominance of each type of cell varies from case to case, but the total amount of junction tissue is proportional to the rate of growth of the cancer or to the defence which is being offered against invasion. Slowly growing cancer has much, quickly growing cancer has little junction tissue. It has been argued that the rapidly growing neoplasms grow over the junction tissue, and so there is little; the only counter to this is to consider that the cancer overgrows the junction tissue because it is inadequate. This junction tissue is frequently termed the stroma; stroma suggests a helpful adjunct to the cancerous process. I wish to point out the possibility of an opposite rôle. The literature shows a diversity of opinion on the relative action of radiation on this tissue and on the cancer cells. Dyroff⁷ concludes that though the surrounding tissues show definite changes after radiation, yet these changes are less and occur later than the changes in the cancer cells. On the other hand, Roussy⁸ notes that there are severe changes in the surrounding tissues but variable and patchy changes in the cancer cells. In the example given—radio-sensitive tongue growth with radio-resistant metastases—the sensitivity is directly proportional to the amount of junction tissue. The primary growth is usually rich in junction tissue, the gland metastases usually poor.

Our experiments appear to strengthen this view, though final proof is not claimed. There is evidence from chemical analyses and histological appearances that the selenide is localised in the junction tissue and not in the cancer to the same extent. Numerous estimations in this laboratory, as in most others, have shown that the cancer contains little, the spleen, kidney, and liver much lead.¹⁰ The colloid would appear to be extracted from the blood by the cells of the reticulo-endothelial system throughout the body and by the cells of this system, the macrophages, which migrate to, or proliferate in the junction tissue. Now, deep X rays and gamma rays can ionise selenium⁶ and, since the toxicity of the members of the selenium group is increased by greater dispersion the ionised selenium is thought to destroy the cell which contains it. If mice implanted with Twort carcinoma in the right flank are treated with radium after injection with lead selenide, few macrophages are found in the junction tissue and few star cells in the underlying liver. Similar treatment, but substituting a non-ionisable guaiacolate, shows more macrophages in the junction tissue and many star cells in the liver. These cells are demonstrated by intravital staining with Indian ink. It is considered that the increase of growth in the cancer after applying radiation to selenide-sensitised tissue is due to this damage to the junction tissue. The damaged junction can no longer inhibit the growth of the neoplasm.

Though the views of Besredka on the importance of the local cellular as opposed to the general cellular and humoral defences are not universally accepted, most unbiased observers agree that this concept of local immunity is the only one which explains many problems. Such a local defence appears to be a factor of importance in the cancer problem, especially from the chemotherapeutic and radiological standpoints. It has long been known that surgical removal of a primary growth might be followed by more rapid growth of the metastases; Besredka's theory gives an explanation; surgical removal also removes the

* Ionisation is to be differentiated from secondary radiation; the latter may be found to be helpful, as will be shown in an experiment below. Ionisation of the metalloids selenium appears to render it very toxic.

protective junction tissue. There is no other explanation at present. Similarly, the apparent "stimulation" of outlying metastases after "successful" radium application to the primary growth can be explained as damage to, or inhibition of the junction tissue from too heavy a dosage.

A different explanation is current—that there exists a stimulating dose somewhere at the periphery of the radiated zone. That there is a stimulating dose appears certain, but this dose is very small and has a narrow range. If stimulation were the explanation, then metastases should be stimulated at about equal distances from the primary, and contemporary recurrences should roughly be symmetrically arranged around the primary. This is not the case; recurrences are found quite near to, and at a long distance from the radiated zone, and it is very difficult to believe that the proximal and the distal metastasis each received this very small stimulating dose. On the whole the first explanation is considered the more likely, especially as it explains the "stimulation" which follows surgical removal, for here there is no possibility of radiation stimulation. This conception implies that, though the junction tissue fails in the end to prevent invasion and metastasis, it still keeps up its inhibitory action, both on the primary and on the outlying metastases.

The General Defence.

Local defence, as conceived from Besredka's theory and applied to the junction tissue, cannot be the only defence mechanism against the proliferation of a malignant neoplasm. Evidence for a general defence is obtainable from the behaviour of implanted cancer in animals and from clinical observation of cancer patients treated by medical methods. Successful treatment of cancer in man is accompanied by definite changes in the blood¹¹—increase of small lymphocytes and eosinophil leucocytes and a diminution of that lipase which can split tributyrin. In addition we find more or less intense fibrosis around the growth and sometimes calcification in and around it. So far as can be said at present, no case of cancer in which these changes have not followed selenide treatment has shown any beneficial response. We call the cases which do not show these changes non-reactive, and the outlook is bad. On the other hand, satisfactory blood changes may occur in cases which do badly in the long run—that is, a reaction has been evoked but was apparently not sufficient to inhibit the cancerous process. In this latter group there is usually evidence of some action; the growths show an unusual softening which frequently amounts to liquefaction. There is a fair amount of evidence other than this that the small lymphocytes and the eosinophils play an important rôle in cancer.

The evidence for participation of the reticulo-endothelial system in the general defence mechanism (in contradistinction to the action of the cells of this system, the macrophages, in the junction tissue) is abundant. When the activity of the system is diminished or paralysed by blockade—that is, when every cell has completely filled itself with the particles of an electro-negative colloid extracted from the blood stream—the implantation of cancer is facilitated. Erdmann¹² found that a certain number of tumours resulted from inoculation of cell-free filtrate of rat cancer and from chloroformed implant after blockade; this never occurred in the intact animal. Several observers^{13,14} have found that mouse cancer could be successfully implanted into rats after blockade, whereas this never happens otherwise. A similar result has been found to follow partial removal of the reticulo-endothelial system, as occurs after splenectomy (until sufficient time has elapsed for regeneration) and after prolonged X radiation of the whole animal. Thus, Brüda¹⁵ found that mouse cancer could be successfully implanted in rats after 30 minutes' radiation and within two weeks after splenectomy. On the other hand, certain virus cancers will not take after previous X radiation of the site of the implant; this is considered to be due to destruction of the

fibroblasts, which are the necessary "culture medium" for these cancers. This same explanation has been given for the regression of implanted cancer in mammals after previous X radiation of the site, but this is wrong, for Vorländer¹⁶ has shown that in rats the regression is accompanied by an ingrowth of fibroblasts into the regressing implant. The failure of mammalian implants to take after radiation may possibly be more correctly explained by a stimulation of the local mesoblastic defences, for it will be shown that such a stimulation actually occurs. Zacherl¹⁷ noted that large doses of radiation crippled the reticulo-endothelial system like the blockade, and measured the damage by noting the diminution of the power of storing an inert electro-negative colloid. Large doses of radiation therefore appear to interfere seriously with the defences against neoplastic proliferation, and this defence is largely the rôle of the reticulo-endothelial system. Brüda¹⁸ found that the plasma of splenectomised animals is a much better culture medium for cancer cultures than the plasma of the intact animal. Further evidence of the protective action of the spleen appears from the inhibiting power of spleen extract of rabbits "vaccinated" by injections of cells of mouse cancer against the taking of this same mouse cancer in mice.¹⁹ Similarly, it had been found that an extract of rabbit spleen which has been stimulated by small venous doses of an inert colloid also inhibits the implantation of cancer.²⁰ The active principle of this stimulated spleen has been termed mesochymin; it inhibits the taking of implants, but has little or no action once the graft has really taken.

There are two ready methods of testing the reactivity of the reticulo-endothelial system as a whole and noting the variation in its activity which results from radiation and chemotherapy.

1. Kaufmann's test.²¹ This is the response of the body to a constant irritant, a cantharides blister of constant size applied for a constant time. The amount of fluid and the number of lymphocytes and monocytes per c.mm. are noted. It is found that cancer patients yield fewer lymphocytes than normals, and that as cachexia progresses the yield further diminishes. Heavy dosage of radiation diminishes the number of lymphocytes but weaker dosage increases it. Mild X radiation of the spleen and ultra-violet radiation of the skin both increase the response in the direction of normality.²²

2. Freund's and Kaminer's test.²³ The serum of non-cancer cases produces an appreciable cytotoxicity of a suspension of cancer cells; the serum of patients with cancer has less or none of this action. Zacherl²⁴ has confirmed this test and has found that, though heavy X radiation lowers what response there is, lesser doses tend to increase the response in the normal direction. That this, again, is due to stimulation or depression of the reticulo-endothelial system would appear from Perachia's²⁵ finding that Freund's and Kaminer's test became negative after splenectomy.

It is suggested that instead of guesses at the response which is considered likely in any cancer—e.g., so many kilovolts or so many milligramme-hours—the reactivity of the patient should be tested by a small dose of radiation on the cancer. By testing the patient before and after this trial radiation it should be possible to determine more accurately the patient's reactivity and thus modify the dosage. It should also be possible to measure the responses and, it is hoped, watch the reactions become more normal as improvement follows. Then, too, those substances which have been shown to exert an action on the junction tissues—selenide of lead and certain fluorescein derivatives²⁶—should be carefully employed. The selenide must not be used before radiation.

Summary.

There is plenty of evidence that radiation affects the cancer cell adversely, probably by inhibitory action on mitotic division, and thus prevents the continuity of the cancer process. It is here considered that this immediate action may be less important

than, or even be produced by, the mediate action of radiation which takes place: (1) locally in the junction tissue, a stimulation of its defence; (2) generally in those parts of the mesoblastic tissues which are concerned with defence mechanisms, especially certain cells of the blood and the cells of the reticulo-endothelial system.

Acceptance of these views will entail further modification of radiation technique in the direction of smaller doses applied for longer times, or at repeated intervals, and also greater screenage. This is the trend of radiation therapy, except teletherapy, which is still under trial in this country, though it has been discarded in others. A fresh viewpoint may help to prevent the disappointment for which the current conception of radiation and the resultant technique are responsible.

It is impossible to refer to all who have afforded some of the data on which this paper is based, as they are too numerous. Some have been noted in the references. Some are indirectly due to Dr. W. C. Stevenson, of Dublin, and some to Dr. J. A. Murray and the staff of the Imperial Cancer Research Fund. I am much indebted to my assistants of the Bristol Royal Infirmary Cancer Research Laboratory.

ANGINA PECTORIS AND CORONARY DISEASE.

By DOUGLAS HUBBLE, M.B. LOND.

It might be thought impossible, after a century and a half of research, to devise a new theory of the causation of angina pectoris, but quite recently a reputable American author¹ conceived the idea that the pain in angina pectoris was due to the stretching of the coronary arteries following the rupture of calcareous plaques in their walls. Other theories which are equally improbable can be unearthed in the literature, and any theory advanced must be scrutinised in the light of the fact that undoubted angina pectoris has now been described in association with a wide variety of pathological states.

These conditions include coronary artery disease, aortitis, aortic regurgitation, severe anaemia, myxoedema, paroxysmal tachycardia, and arterio-venous aneurysm. Keefer and Resnik,² in a compre-

hensive review of the subject, support the view that in all these conditions the common factor is an anoxemia of the myocardium. I accept this theory, but it is interesting to review those theories of the pathogenesis of angina pectoris which are, at the moment, most strongly supported. They incriminate three anatomical structures—the coronary arteries, the aorta, and the myocardium.

The Coronary Arteries.

This theory, in its original form, stated that the underlying factor in all cases of angina pectoris was disease of the coronary arteries. It is the oldest of all theories and was first advanced in the day of Jenner and Parry; and Huchard,³ who made brilliant investigations in support of this theory, wrote—

"Cette énumération n'est pas inutile pour donner la preuve qu'un auteur qui voudrait s'approprier, avec la priorité de cette théorie, le labeur de tout un siècle, commettrait un déni de justice à son profit."

Although it has been strongly assailed, this theory has received a great fillip in recent years by the widespread recognition of the syndrome of coronary thrombosis. Parkinson and Bedford,⁴ in their very able discussion of this condition, write: "we believe that the study of coronary thrombosis has nailed angina for ever to the tree of decaying coronary arteries." Without supporting this view in its entirety it is true that the pain of cardiac infarction and the pain of angina pectoris are sufficiently similar to suggest a common origin for both conditions. Allbutt⁵—writing, however, in 1915 before the syndrome of cardiac infarction was thoroughly appreciated—stressed the differences between the two conditions, and many authors since his day have elaborated them.

There were two original objections to the complete acceptance of the coronary theory. It was soon recognised that many cases which were found at post-mortem examination to have extensive coronary disease, even with obstruction, had no history of attacks of angina. Investigations into the coronary circulation have done away with this first objection. It is now known that the anastomosis between the various branches of the coronary system is often very extensive and sometimes, even in an acute obstruction, so free that the supply of blood to the myocardium is not seriously jeopardised and no anginal pain develops. The second objection is not so easily dismissed. Cases of angina pectoris in which there is no demonstrable lesion of the coronary arteries have frequently been described in the literature. These cases have been examined very critically by many authors and the conclusion is inevitable: angina pectoris can occur in the absence of any coronary lesion.

Coronary spasm.—To account for these cases the ingenious and attractive idea of a spasmodic constriction of the coronary arteries was mooted, but it has remained a hypothesis which is not very susceptible of proof; and if the myocardial anoxemia theory is accepted it seems to do away with the need for any theory of coronary spasm. Keefer and Resnik² oppose this further development of the coronary theory on other and more debatable grounds. Firstly, they say that it "is difficult to understand how vasoconstriction could affect a coronary artery which was already altered by coronary sclerosis." But surely the theory of coronary spasm was advanced to account for those cases in which there was no demonstrable coronary disease. No one, to-day, postulates vasoconstriction in a calcareous artery. It is enough for the production of angina pectoris that when the myocardium calls for an increased blood-supply the diseased artery fails to dilate. Again they say, "one would expect, if coronary spasm were the actual cause of angina pectoris, to find fairly frequent examples of myocardial infarct without organic obstruction of the coronary arteries." This seems an unreasoning argument. Is it rational to expect a temporary and relative diminution in the blood-supply of the myocardium to result in

the production of a myocardial infarct? They have previously admitted that a permanent and absolute occlusion of a branch of the coronary circulation may not result in an infarction owing to an adequate coronary anastomosis. In their third objection to the theory of coronary spasm it seems likely that they are on surer ground. They quote the animal experiments of Anrep and Segall,⁸ which prove that vasoconstriction of the coronary arteries is due to vagal action—and stimulation of the vagus is always accompanied by a slowing of the heart rate—and they quite rightly point out that there is no characteristic alteration of the pulse-rate in angina, and certainly no constant deceleration.

To sum up the present position with regard to the coronary theory one may say that, although a coronary lesion is present in most cases of angina pectoris, yet it is impossible to accept the theory as a complete explanation for all cases of angina pectoris; and that the occurrence of coronary artery spasm as a factor in the causation of angina pectoris is by no means proved, and is an unnecessary hypothesis unless there is proved to be no condition present which is capable of producing an anoxæmia of the myocardium.

The Aorta.

Clifford Allbutt⁹ first incriminated the aorta. His view was that the pain of angina was due to tension of the first part of the aorta, which was invariably the seat of an inflammatory lesion. Sudden death occurring in angina was in his opinion due to vagal inhibition of the heart's action. The main support for this theory rests on the finding of an aortic lesion in most cases of angina pectoris, and it is undoubtedly true that the post-mortem records of patients who have suffered from angina during life show, as a rule, either aortic atheroma or syphilitic aortitis. The relevant objections to this theory may be briefly stated:

(a) Many cases of angina pectoris have been recorded in which no disease of the aorta was demonstrated after death. Allbutt confessed, for example, that he was unable to account for the occurrence of angina in aortic regurgitation of rheumatic origin.

(b) Aortic lesions occur very frequently without anginal symptoms. For instance, on this theory, it is difficult to account for the rarity of angina pectoris in aneurysm of the aorta.

(c) The average age incidence of syphilitic aortitis is a decade earlier than the average age incidence of angina pectoris.

(d) The theory of death from vagal inhibition is inadequate. Lewis⁷ writes: "To accuse the vagus when unexpected syncope terminates life, in the absence of clear evidence of its responsibility, is unjustifiable." It is probable that sudden death in angina pectoris results from ventricular fibrillation, and there is no experimental evidence to show that fibrillation of the ventricle is dependent on vagal stimulation. Again, there is no evidence that the vagus is stimulated during an attack of angina pectoris; there is neither slowing of the heart-rate nor any evidence of auriculo-ventricular block.

(e) The high rate of incidence of aortic changes accompanying angina pectoris is well explained by an alteration in the coronary circulation. Aortic atheroma is often accompanied by coronary atheroma and in syphilitic aortitis the mouths of the coronary arteries are often obstructed. It has also been recently suggested by East and Bain⁸ that advanced atheroma of the aorta results in a diminished elasticity which impairs the head of pressure regulating the coronary circulation.

Wenckebach has given his strong support in recent years to the aortic theory without, however, adding very much to the evidence already marshalled by Allbutt.

The Myocardium.

There has been a growing consensus of opinion in this country and in America that, whatever may be the exact cause of the pain in angina pectoris,

the original impulse arises in the cardiac muscle. Three main theories have been advanced which involve the myocardium.

(1) *Myocardial exhaustion.*—Sir James Mackenzie was responsible for this theory,² which suggests that the underlying factor in angina pectoris is an acute cardiac exhaustion. This hypothesis is an example of the over-simplification which was Mackenzie's tendency in later years in his endeavour to strike to the foundations of a subject. It is obvious that he was fully convinced of the importance of coronary disease as a factor in angina but, being puzzled by those cases in which the coronary arteries were not involved, he resorted to the idea of myocardial exhaustion. This conception is, in any case, too vague to be satisfactory, but there are also many objections to it.

Angina pectoris declares itself in the heart, which has a reasonably good reserve and if, later, that heart should fail (true myocardial exhaustion) then the anginal attacks tend to disappear. Why should angina appear in a heart which is exhausted by reason of coronary disease, aortitis, or aortic insufficiency, and yet be invariably absent in a heart which is exhausted by the handicap of a stenosed mitral valve? In his last book,¹⁰ written just before his death, Mackenzie says no word of this theory.

"Although," he writes "one can trace angina pectoris to the heart muscle, and although we can recognise from the various illustrations given that voluntary muscles made to contract when deprived of blood give rise to pain, and although it can be demonstrated in many cases of angina pectoris that the heart muscle was deprived of blood and that pain resulted when there was a demand for more blood, as an effort, yet it is not quite clear how these impulses, which could not arise from a greatly increased number of muscle cells contracting, give rise to pain."

He had left London for St. Andrews and turned his attention from the cause of angina to the actual mechanism of pain-production.

(2) *Myocardial distension.*—Poulton,¹¹ in an endeavour to bring anginal pain into line with what may be called the Guy's Hospital theory of pain-production in hollow muscular organs, writes of angina pectoris: "On the analogy of œsophageal and gastric pain, cardiac pain would be due to a tonelessness and consequent stretching of the muscle, and amyl nitrite may possibly act by stimulating the muscle to contract down on its contents." It is possible that the pain of congestive heart failure may be brought about in this way,¹² but there are several reasons for believing that the pain of angina pectoris, being different in character, has an entirely dissimilar origin. The objections to this theory are:

(a) That the pain of angina pectoris tends to disappear when congestive heart failure—i.e., tonelessness and stretching of the muscle—supervenes.

(b) Many cases are recorded which suggest that when cardiac infarction occurs in a heart which is already failing—i.e., in a distended heart muscle—the typical anginal pain is absent.

(c) There is no evidence of any sort to show that amyl nitrite causes the cardiac muscle to contract down on its contents. According to Cushny¹³ and Dixon,¹⁴ amyl nitrite has no direct action on the heart muscle, except in toxic doses in the frog when the contractions are weakened—as would be expected from the action of the drug on unstriated muscle.

(d) There seems to be no special reason, except on morphological grounds, why the origins of gastric and cardiac pain should be analogous, even if Poulton's explanation of gastric pain is accepted. The structure, function, and properties of the two muscles are so dissimilar. The fact seems to be that there is no condition occurring in the stomach or œsophagus which is at all comparable to angina pectoris.

(3) *Myocardial anoxæmia.*—This last theory maintains that the pain of angina pectoris arises in the cardiac muscle and is invariably due to temporary oxygen-lack. Stated more broadly,

anginal pain arises from a disproportion between the oxygen demands of the cardiac muscle and its available oxygen supply. This definition thus includes the pain of coronary thrombosis. This theory is but an extension of that development of the coronary theory which says that angina is due to an inadequate coronary circulation; it is more precise in definition and it spreads the net a little wider so as to include cases not covered by the coronary theory. It is no new theory, but it has recently been elaborated by Keefer and Resnik² in an admirably comprehensive review (to which I am indebted); it does not differ so deeply from the coronary theory as these authors suggest, but it is definitely a distinction which is worth emphasising. In a review of the literature they state that "when the facts are complete it is possible to demonstrate anoxæmia in practically every case." That this is so in angina with coronary artery disease is plain, but in many other conditions the anoxæmia factor is not so obvious. Three examples given by Keefer and Resnik may be quoted. A common condition with which angina is sometimes associated is aortic insufficiency, and both Allbutt and Mackenzie were puzzled to explain this connexion; Smith and Miller¹⁶ have shown that the blood flow through the coronary arteries was actually decreased in experimental aortic insufficiency in dogs and that this disease was due to a lowering of diastolic pressure—sufficient evidence that in aortic regurgitation there is an anoxæmia of the myocardium. Several cases of angina occurring in association with severe anæmia have been recorded, and many observers have pointed out that the attacks of angina were dependent on the degree of anæmia and that as the blood picture improved the angina disappeared. In these cases it is impossible to escape from the conclusion that the angina must be dependent on a diminished oxygen-supply to the cardiac muscle. Again, attacks of angina have been described in cases of arteriovenous aneurysm, a condition which results in a lowering of diastolic pressure and a diminished flow through the coronary arteries.

If it is accepted that anoxæmia of the myocardium is present in almost every case of angina pectoris can it be shown that this condition will produce the symptoms of angina? It has to be admitted that while the evidence for this is strong, it is not conclusive, nor does it seem likely that direct proof will ever be available; but the case for this theory has been enormously strengthened by the recognition of the syndrome of coronary thrombosis—a condition which causes acute anoxæmia of part of the myocardium. The distinction between the pain of simple angina pectoris and of coronary thrombosis is solely one of degree, and in essential characteristics the pain in the two conditions is identical. The experiments of MacWilliam and Webster¹³ with skeletal muscle provide a suggestive analogy. They found that when the blood-supply of the arm is cut off by constriction pain is not experienced, even for 20 minutes, providing the arm is at rest, but that when the muscles are made to contract the arm is very much more quickly fatigued than the normal arm, and that when the fatigue-point is reached there is very severe pain. If this analogy is permitted, anginal pain may result because the cardiac muscle has to go on contracting notwithstanding an anoxæmia. This theory also provides an adequate explanation of the sudden death which takes place frequently in angina pectoris. It is now generally believed that the sudden death is due to ventricular fibrillation, and Sir Thomas Lewis showed 20 years ago¹⁷ that ligation of the coronary arteries in animals caused ventricular fibrillation and death. It seems probable therefore that instant death due to ventricular fibrillation is particularly likely to develop in conditions which produce anoxæmia of the myocardium. This theory does not explain all the problems of angina pectoris and several questions remain unanswered but, to an impartial observer, it is certain that there are many fewer objections to this than to any other theory and

that it is, at least, the one theory which is not at any point inconsistent with the enormous mass of recorded fact.

Coronary Thrombosis and Angina Pectoris.

There has been much discussion concerning the distinction between the pain in simple angina and the pain in cardiac infarction. Allbutt,⁵ for example, in maintaining an aortic origin for angina, stressed the differences in the two conditions, while others have pointed to their essential similarity as a proof of the coronary hypothesis. Much has also been written of the differential diagnosis of the two conditions, and confusion has arisen because insufficient distinction is made between coronary disease with and without cardiac infarction. Lambert,¹⁸ for example, in an otherwise excellent article on cardiac pain, gives a differential diagnosis as follows.

Coronary Disease.

Pain often epigastric.
Pain of long duration.
With dyspnoea.
Occurring at night.
Unrelieved by nitrites.
Râles in lungs.
Fall of blood pressure.

Arrhythmias present.

Angina Pectoris.

Pain sternal.
Pain temporary.
Without dyspnoea.
Brought on by effort.
Relieved by nitrites.
No signs in lungs.
Blood pressure unaltered or raised.
Arrhythmias absent.

It is obvious that the last four signs in the first list are not signs of coronary disease at all, but signs of cardiac infarction and, as the first part of this article has amply demonstrated, angina pectoris itself is often evidence of coronary disease.

The differential diagnosis between simple angina pectoris and cardiac infarction is sufficiently obvious. In the latter condition the duration of the attack, the collapse, the pyrexia, the fall of blood pressure, the nausea and anorexia, and the signs of congestive heart failure in the liver and lungs soon establish a diagnosis beyond doubt. But the diagnosis between a shower of anginal attacks which is the prelude to cardiac infarction and attacks of simple angina pectoris is not so straightforward, yet it is important, from the point of view both of prognosis and of treatment, to make this diagnosis. The following case illustrates well the various diagnostic points.

The patient was a male aged 63. On May 13th, 1929, he complained of chest pain which had started three weeks previously. The pain was situated over a wide area between the lower end of the sternum and the left nipple, and radiated up to the jaw and the left side of the head. The pain commonly started when he was walking but occasionally the onset bore no relation to any effort; in fact, on the morning he was first seen, the pain had come on at 6.30 while he was lying in bed. Its character was gripping and constricting, and it was moderately severe. The duration was usually a quarter of an hour, but occasionally it lasted as long as three hours. He stated that during the previous winter he had been increasingly dyspnoeic on exertion. On examination his heart was enlarged, with the apex-beat half an inch outside the left nipple line, and the sounds were distant. His blood pressure was 162/104 mm., and there was a trace of albumin in his urine. The pulse-rate was 68. The brachial artery was thickened and easily palpable. A diagnosis of angina was made, though it was realised that the symptoms were slightly atypical. He was put to bed and given tabellæ of trinitrin (gr. 1/100), which he was told to take at the onset of his pain. This he did, and when next seen he said that one tablet gave him complete relief from his pain within five minutes but that his pain invariably returned in two hours. This relief given by nitrites was thought to confirm a diagnosis of true angina. Four days later he stated that his pain was distinctly more severe and more persistent than when he had come to bed, and the fact was puzzling. The next night at 11.30 he had a severe attack of his pain, which was not influenced in the slightest degree by trinitrin; this attack for the first time was accompanied by dyspnoea and at 5.30 the next morning he had a similar attack which persisted until he was seen at 11 A.M., in spite of the fact that during these few hours he had taken gr. 1/25 of trinitrin and inhaled vigorously a 5 minim capsule of amyl nitrite. At midday his pain became agonising; he was pale, cyanosed, sweating, and restless. His temperature was subnormal, his pulse-rate, though regular, had dropped to 50, and his heart sounds were weaker than before his acute

attack. His systolic pressure had dropped to 100 mm. It was then realised that his heart was infarcted, and he was given morphia and all vasodilators were withdrawn.

Next day there was no doubt about the diagnosis. He showed the characteristic appearance of cardiac infarction. His tongue was heavily furred, he had vomited once, there was no desire for food; his stomach, he said, was unsettled. His blood pressure was 103/80 and his temperature was 101°. His pulse was regular and the rate had risen with the pyrexia to 74. The heart sounds were weak. There were no signs of pericardial friction or passive congestion. His pain had disappeared but there was a resultant heavy soreness and stiffness over a wide area of the chest and the left side of the face. He was emphatic in his opinion that the only thing that differentiated his pain of the day before from the pain of the previous three weeks was its severity. Situation and character were identical. Two days later he desired to defecate, and having tried to use the bed-pan and failed he was allowed by his nurse to rise from his bed and use the commode. Ten seconds after getting back to bed he complained of an acute pain in his chest, collapsed immediately, and died 70 hours after the onset of the infarction.

This is clearly a case of coronary thrombosis and cardiac infarction with prodromal anginal attacks of increasing severity lasting over several weeks. Parkinson and Bedford⁴ mention nine cases of cardiac infarction with prodromal anginal attacks; they refer to it as the ingravescens anginal state and it corresponds to the status anginosus of earlier authors. It is impossible to be sure what is happening in the heart in the prodromal anginal attacks; either the attacks are dependent on a gradual narrowing of the lumen of a main branch of the coronary circulation or, less probably, they are due to the thrombosis of small branches of the coronary arteries—branches too small to give the characteristic picture of cardiac infarction, owing to an adequate collateral circulation. It is certain that in patients who have anginal attacks the coronary circulation is always hovering on the edge of inadequacy and the cardiac effort which may produce an attack depends on the condition of the coronary arteries.

When the coronary arteries are but slightly diseased, strenuous effort may be necessary to bring about the relative anoxæmia of the myocardium; when the walls of the arteries are grossly damaged they will be unable to adjust their lumen to the call for an increased blood-supply, and only slight effort is needed to produce an attack. In coronary thrombosis the blood-supply is definitely obstructed and the attack may occur when the heart's requirements are minimal—with the patient in bed at rest.

Diagnosis of Prodromal Anginal Attacks.

From the point of view of treatment it is important to differentiate these attacks from simple angina pectoris. Unlike typical angina, the attacks may come on independently of effort or emotion and are not relieved in a short time by absolute rest. The patient himself realises this, and it is unusual to find the complete immobility associated with angina. The initial attacks may be of short duration, but in hours or days they return with increased frequency and greater severity until they merge into a prolonged anginal state which culminates in typical cardiac infarction. The whole process may occupy days or weeks. The attacks are often, at their height, accompanied by dyspnoea. Some authors have attempted to differentiate these prodromal anginal attacks from simple angina by differences in the character, the position, and the intensity of the pain, but, as in the case quoted above, these points usually offer no help in diagnosis.

The Reaction to Nitrites.

Great stress has been laid by various authors on the fact that the nitrites, while giving relief in angina pectoris, give no relief in coronary thrombosis or its prodromal anginal attacks, and this fact is often quoted in the differential diagnosis. A consideration of the case quoted above does not, however, bear this out. The nitrite relieved the patient's pain for the period of its pharmacological action, and when the effect of the drug wore off his pain returned with the same or greater intensity. This reaction

to nitrites, if proved to be constant, will be enough of itself to give warning of the threatening thrombosis.

The mode of action of nitrites in relieving the pain of angina pectoris is still doubtful; they probably act both by lowering the systolic blood pressure and by dilating the coronary arteries—i.e., at the same time diminishing the work of the heart and increasing its blood-supply. It is impossible to say which of these two actions is the dominant one, but it is probably correct to say that the nitrites can have little or no vasodilating effect on grossly diseased coronary arteries. In the case quoted above the nitrite may have relieved the patient's pain by lowering the blood pressure and lessening the work of the heart, but it is also probable that it had a vasodilating effect, not on the artery in which the thrombosis was gradually occurring, but on other vessels in the collateral circulation, thus relieving temporarily the anoxæmia in that part of the myocardium which was threatened with infarction. Nitrites are obviously contra-indicated in cardiac infarction, as many authors have pointed out, but a consideration of this case suggests that they are also dangerous in cases of ingravescens coronary thrombosis; it is noteworthy that after the temporary relief from the nitrite had passed the pain returned, often with increased severity. It seems probable that by lowering the blood pressure the nitrite accelerated and aggravated the cardiac infarction, for animal experiment has shown that to get the largest area of infarction it is always necessary to lower the blood pressure artificially.¹² This demonstrates the importance of making a differential diagnosis between angina pectoris and a developing coronary thrombosis; for the remedy which is beneficial in simple angina pectoris is actually dangerous (though apparently of temporary benefit) in the prodromal anginal attacks of coronary thrombosis.

The diagnosis of these prodromal anginal attacks rests, then, on five points: (1) the onset unrelated to effort; (2) the failure of rest to relieve the pain; (3) the recurrence and increasing duration of the attacks; (4) the accompanying dyspnoea (not invariable); (5) the typical reaction to nitrites.

When the attacks proceed to cardiac infarction then the diagnosis is straightforward, thanks to the careful researches of recent years in America and in this country.

MANFIELD ORTHOPEDIC HOSPITAL.—The annual report of this institution, in the outskirts of Northampton, states that last year the work expanded in all departments, 235 patients were admitted and over 1000 out-patients were treated. Satisfaction is expressed that patients who are not cripples in the ordinary sense of the word but who suffer from deformities and disabilities which would ultimately result in crippling, are being dealt with at an early stage.

THE SIGNIFICANCE OF SWEATING IN MAN.*

BY YAS. KUNO,
PROFESSOR OF PHYSIOLOGY.

(From the Physiological Laboratory, Manchuria Medical College, Mukden.)

THAT the regulation of the temperature of the body is almost the sole object of sweating has been a current view for many decades and, so far as I am aware, no serious objection has ever been raised against this opinion. I have, however, long been sceptical about its truth, as medical writings often state that sweating may be provoked not only by an increase of the temperature of the surroundings or muscular exercise but also by emotion or mental stress. It is quite reasonable that the former, which always result in an increase of the temperature of the body, cause sweating—a process of heat elimination. But we can hardly understand why the latter, which have little bearing on the body temperature, should also be a cause of sweat. There seems to be room still left for the assumption that sweating may have some other purpose.

In this laboratory my collaborators (Dr. K. Ikeuchi, Dr. T. Kosaka, and others) and I have been engaged in research work on the subject of sweating for about eight years. As a part of this, we made experiments with the purpose of answering the above question, and recently we have come to the conclusion that sweating in man is, in respect of the features of secretion as well as of its physiological significance, not uniform all over the body surface, and that it should be classified at least into two different categories. In the present paper I shall discuss the essential points of our experiments. All were carried out on man. The measurement of sweat was not made on the whole body surface, but on an area of skin of about 20 sq. cm. The amount of sweat discharged from this area every five minutes was determined and, using this amount as the unit, changes in sweating were observed for considerable periods of time. Such a measurement was, as a rule, carried out on two different parts of the body surface at the same time. The portions of the skin at which the measurements were to be made were covered with celluloid dishes, 20 sq. cm. in diameter, furnished with two side tubes through which a dry air current passed over the skin and was introduced into tubes containing calcium chloride. The gain in weight of the tubes was measured every five minutes. The temperatures of the same portions of the skin and in the rectum were determined by the thermo-couple method.

Classification of Sweating in Man.

Using this method, we observed sweating provoked by many different causes. The sweating caused by an increase of room temperature may be regarded as the most common type. Fig. 1 shows one example of such experiments, in which the measurements were made at the chest and the thigh. The tracing in this figure lettered by Tm represents the room temperature; SA, the amount of sweat per 20 sq. cm. per five minutes at the chest; SB, that at the internal surface of the thigh; TA and TB, the skin temperatures measured at the same parts of the skin, and Tr, temperature in the rectum. Sweating begins some 30 minutes after the rise of room temperature and increases rapidly. Though the amount of sweat is very different between the two parts of the skin, the time of the outbreak of sweating is almost the same, and its further changes also coincide. A great number of such experiments were made at many different parts of the skin, but the results were almost the same as shown in the figure.

In another series of experiments local heating of one arm or one leg with dry hot-air baths was used to cause sweating. In this case, sweating also appeared on the whole body surface and was never restricted to the heated portion alone. This may be seen in Fig. 2. In this experiment the left leg only was exposed to a hot-air bath, the temperature of which is indicated by the tracing Tm. Sweating was measured at the corresponding portions on the outer surfaces of both legs, one was heated (SA), and the other was not (SB). Tracings SA and SB show that sweating occurred at the same time and changed in the same manner at these two parts, the only difference between the two being that the amount of sweat was greater on the heated side.

According to these experiments, the sweating caused by heating inevitably appears all over the body surface and never locally, even when the heating is confined to a small portion of the skin surface. But the palms of the hands and the soles of the feet do not conform to this general rule. These parts are those where sweat glands are present most densely, and our experiments proved that, in the state of so-called insensible perspiration, the amount of water discharged from the skin was distinctly larger at these parts than at any other parts of the body surface. It is peculiar, however, that the perspiration from these parts does not increase at all from ordinary thermal causes; in other words, the palms and the soles do not sweat under high atmospheric

Sweating caused by increase of room temperature.

temperature which causes a profuse sweating on all the remaining parts of the body surface. This is shown in Fig. 3. In this experiment sweating was measured on the palm (SA) and on the chest (SB), and the room temperature (Tm) was raised. At the beginning the amount of perspiration was much larger on the palm than on the chest, but the former did not change when the room temperature became high, while a considerable sweating appeared on the chest. Our own experiences agree with the results

* Translation of a lecture given by the author at the fourth annual meeting of the Japanese Association for the Advancement of Science.

of this experiment, because the sweat may run down from the forehead or many other parts of the skin in the summer, but never from the palms or the soles.

This does not mean, however, that the sweat glands of the palms and the soles have no ability to increase their secretion. [Though they do not react

sweating on this part, but quite sufficient to do so on the palm. All these accounts and many other similar experiments show clearly that the palms and the soles sweat extremely easily as a result of mental stress. A phrase commonly used in the Japanese language is "with sweat in the clenched hands," by which is meant "with suppressed excitement" or "with breathless interest."

With respect to the causation of sweating as well as to the distribution on the body surface, the human sweat glands are, therefore, to be classified clearly into two groups: (1) The sweat glands present on the palms and the soles have the characteristic of permanent secretion and react with an increased secretion to mental or sensory stimulation but not to rise of temperature in the environment. (2) The sweat glands distributed all over the remaining parts of the body surface show little or none of this permanent secretion or "insensible perspiration." They are not responsive to moderate mental stimulation, but profuse sweating occurs from them when the temperature of the environment rises. One phenomenon is, however, common to these two different sets of sweat glands—i.e., every sweating, whenever it occurs, appears universally over its own respective district and is never confined to any single part in its area. For brevity I will designate the sweating from the former set of sweat glands as "mental or

Sweating caused by local heating.

to common thermal causes, they are able to increase the secretion as a result of many other causal agents. For example, local heating applied to any part of the skin surface, if only it is of an extreme degree, can provoke profuse sweating on the palms and the soles. Besides this, we have also occasionally found that some kinds of pain or some unusual feelings, such as desire to urinate or application of Esmarch's bandage, may be the cause of this sweating. Any intense sensory stimulation seems, therefore, to be able to provoke sweating at these parts.

The most adequate cause for this sweating seems, however, to be mental stress. In our experiments mental arithmetic was used to cause mental stress; its influences on the perspiration on different parts of the body surface were observed and very interesting results obtained. Mental arithmetic caused sweating on the palms and the soles only, and not on other parts of the body surface. This is illustrated in Fig. 4 which shows an experiment of the measurement of the perspiration on both palms. During a period of time indicated by M, mental arithmetic was done. Immediately after the beginning of the mental arithmetic the amount of perspiration started to augment; it increased progressively and diminished soon after the mental arithmetic ended. Changes in the amount of sweat on one palm closely paralleled those on the other. Many other similar experiments proved that sweating on the palms and the soles due to any cause is never restricted to one of them but always appears on all four parts. Fig. 5 shows an example of the simultaneous measurement on the palm and on some other part of the skin, in this case the forehead. Tracings show that the palm sweats considerably from mental arithmetic but that no vestige of sweating is found on the forehead. The forehead is well known to be a part of the skin where profuse sweating sometimes occurs in mental stress. This experiment proves that mental arithmetic is not strong enough to cause

Sweating on the palm and the chest under high room temperature.

psychical sweating," and that from the latter as "thermal sweating."

Physiological Significance of Sweating.

Now arises the question: what is the physiological significance of these two different sweatings? The regional relationship of the thermal sweating on the body surface was observed in the following way. Twenty pieces of filter paper, of exactly the same size and previously weighed, were attached to different parts of the skin, all over the body surface, and hermetically covered with celluloid dishes. The subject was then allowed to sweat profusely in a hot room. Afterwards the papers were taken and again weighed and the gain in weight of each paper was compared. This experiment was made on four men and four women and conformable results were

† Stated in previous papers from this laboratory.

obtained in all. The palm and the sole do not enter into the present discussion, as they are the parts where no thermal sweating appears. With the exception of these two parts, the armpit and the internal femoral region are the parts which sweat least. Generally speaking, the head, the neck, some areas of the anterior and posterior surface of the trunk, and the dorsal region of the hand sweat most. Compared with these parts, sweating on the lateral surface of the trunk and on the greater part of the extremities is remarkably slight.

In addition to this experiment, a simple investigation of sweating was made on the whole body surface on a number of subjects, and we came to the conclusion that the regional distribution of sweating accords closely with the varying necessity of heat elimination from different parts of the body. The following are the reasons for this conclusion: (1) Parts of the skin which have little chance for evaporation of heat sweat least as a rule—e.g., the armpit, the perineal region, the inguinal region, and the internal femoral region. This seems at a glance to be contrary to our daily experiences, because the parts of the skin just mentioned are the very parts which are apt to become wet in hot weather. Experiments have, however, proved that they become wet, not because the sweating is abundant, but because the sweat once discharged evaporates with difficulty. (2) As mentioned above, sweating is, on an average, most abundant on the head, the neck, and the trunk, and much less on the extremities. This seems also to meet the necessity of heat elimination. In the former parts the superficial area is small with respect to the mass; moreover, there are important organs in the cavities and accordingly the necessity of regulation of temperature must be much greater than in the extremities. (3) Sweating is slight on the parts of the skin very rich in subcutaneous fat—e.g., the cheek, the gluteal region, and the mammary region. The cooling effect of evaporation on the whole body may be little at these parts, and it seems reasonable to avoid sweating there. All these circumstances are, therefore, advantageous for the elimination

Sweating on both palms caused by mental arithmetic.

tion of heat, and the theory that the function of sweating is the regulation of the body temperature seems quite correct for thermal sweating.

For mental sweating, however, the theory no longer holds good, because this sweating never appears on exposure of the body to high atmospheric temperature. If this sweating has any physiological significance, it may conceivably be in some relation to mental stress which is its most adequate cause. We have a peculiar habit of moistening the palms of the hands with saliva when muscular exercise is undertaken. This seems to be a habit common to the human race, physiological and not ethnological in origin, because an expression for "spitting on the hands" is found in many different languages. Moistening the surface of the palm would increase the friction between it and the objects with which it comes into contact. Consequently, every sort of muscular work

would be facilitated, not only for this physical reason but also for the physiological reason that the sense of touch becomes acute when friction increases. In human beings mental stress is not necessarily accompanied by muscular work, but it is almost inevitably so in animals, because they become excited only for such reasons as self-defence against enemies and battle for the acquisition of food or for the other sex, when more or less muscular exercise is required. It is, therefore, a great advantage for animals that the pads of their feet should become wet through sweating as soon as they are excited. The sweating on the human palms and soles may be regarded as a phenomenon transmitted from animal life. Even in human beings it is not always useless. It is interesting to note that in some languages—e.g., Japanese and Chinese, perhaps in English too—the expression "spitting on the hands" conveys an implication of general physical and mental stress. It is, therefore, highly probable that this sweating has the function of facilitating physical work.

Effect of mental arithmetic on the perspiration of the palm (SA) and that of the forehead (SB).

of general physical and mental stress. It is, therefore, highly probable that this sweating has the function of facilitating physical work.

The regional differences of sweating were also investigated on the surface of the palm and the sole by means of the method suggested by Eijkmann. The skin surface was well coloured with an alcoholic solution of fuchsin. A piece of thin Japanese paper was laid on it and kept in good contact with the skin, and then mental arithmetic was given. Drops of sweat discharged from the orifices of the sweat glands dissolve some of the dye and leave red spots on the paper. The density of these imprints corresponds to the distribution of the sweat glands in action, and the degree of colouring is roughly proportional to the amount of sweat discharged. By this method it was found that sweating is, in general, profuse on the parts of the palm and the sole which are protuberant and likely to touch objects on grasping or on walking, and much less on the remaining parts. This regional difference is especially striking between the plantar arch and the remaining parts of the sole, so that the former remains almost white while the latter becomes diffusely red. All these circumstances support the view discussed above about the significance of this sweating.

Sweating in Animals.

The degree of sweating on the pads of the feet varies extremely in different mammals, and this difference seems to be related to their habits. Presumably moistening the pads is not very necessary for animals walking on the ground only, but would be of vital importance to those accustomed to climb trees. It is well known that the pads can sweat freely in the cat and the monkey, and little in the dog and rabbit. The horse sweats most easily on the whole body surface, but the plantar regions of the extremities do not touch the ground, and sweating is not profuse on them. On the contrary, the cat sweats on the pads only and little or practically not at all on the other parts of the body. Therefore, so far as these animals are concerned, the significance of sweating on the pads seems to be the same as that of

mental sweating in man. I am anxious to know if this also applies to other animals, but our present knowledge is too limited to enable us to answer this question.

Many experiments have been performed on the cat from olden times, and the conclusions obtained from the results of these experiments play an essential part in the present knowledge of thermal sweating in man. All these experiments were, however, made under the premiss that sweating in man and in the cat are of the same nature. According to the above discussion, the sweating in the cat seems to be classified with mental sweating, and, if so, this premiss cannot be acknowledged. Judging from common-sense, too, sweating on such small portions as the pads can hardly be regarded as effective for the regulation of the body temperature.

Under ordinary circumstances, the amount of water discharged from the palms and the soles per unit of area is five to ten times as much as that discharged from most of the other parts of the body surface, and this seems to be chiefly due to a permanent secretion of the sweat glands. It has experimentally been proved in this laboratory that the diffusion of moisture through the epidermis is very slow. The outer surface of a thick horny epidermis like that of the palm and the sole might clearly become extremely dry and lose its characteristic flexibility if there were no process for supplying it with moisture. The permanent secretion of sweat on the palm and the sole is intended to meet this necessity. As a matter of fact, the epidermis of these parts sometimes becomes stone-hard on account of the thickening of the skin in a corn, or becomes chapped with dryness in cold weather, probably due to an enormous decrease in the permanent secretion owing to the effect of cold. The constant secretion of the sweat glands of the palms and the soles is, therefore, an important process for the protection of the skin.

Conclusions.

The sweat glands of human beings have three important functions: (1) the regulation of the body temperature; (2) the facilitation of physical work; and (3) the protection of the skin.

A CASE OF CONGENITAL RHABDOMYOMA OF THE HEART.

By GEORGE BROWN, M.B., Ch.B., F.R.C.S. EDIN.,

CLINICAL TUTOR, ROYAL INFIRMARY, EDINBURGH;

AND

JOHN GRAY, M.D. EDIN.,

DEPARTMENT OF PATHOLOGY, ABERDEEN UNIVERSITY.

RHABDOMYOMATA are rare tumours, but the heart is one of the commoner sites of occurrence. Solitary growths are rarer than multiple. Uehlinger,³ in 1925, collected 37 cases, 7 solitary and 30 multiple, almost all from German literature. Of these, 25 occurred in the first three years of life and 31 within the first ten years. Tuberos scleriosis in the brain and renal tumours, frequent in the case of the multiple tumours (tuberos scleriosis in 21 of 30 cases, renal tumours in 12 of 30 cases), are not described in the seven cases with solitary nodules, although the brain was not always examined.

The following case occurred in our experience recently.

The patient, a male infant aged 3 months, was brought to hospital on August 8th 1929. Whilst having his evening feed, he was accidentally struck on the left ankle by the buckle of a strap with which his elder brother, a child of about 4 years of age, was playing. The blow was only a slight, glancing one, just sufficient to cause a superficial scratch about one inch long, but the infant, not unnaturally, immediately commenced to cry vigorously. This crying

about lasted for a few minutes, when there was a sudden change, and the child became very pale and ceased crying. The change was so sinister that the mother wrapped him up in a shawl and at once rushed him off to hospital, where he was found to be dead. During the interval between leaving home and examination at the hospital—possibly some five minutes—the child remained quiet, showed no sign of life, and was presumably already dead. At no time during the attack did he appear to have any respiratory difficulty, and there was no evidence of cyanosis.

The child had always been regarded as healthy and normal. He had never suffered from fits or convulsions, and there was certainly nothing to suggest that he was other than what he appeared to be, a normal healthy child in every respect.

Post-mortem Examination.

The body was well-developed and well-nourished. No organ save the heart showed any significant alteration. In particular, no sclerosis or other alteration was found in the brain, and no tumour nodules in the kidneys or elsewhere. The heart was very much enlarged, weighing 130 g. as

FIG. 1.

FIG. 2.

FIG. 1.—Cardiac tumour showing fasciculation. ($\times 50$.)

FIG. 2.—The same. ($\times 900$.)

against a weight of about 25 g. for the normal heart at the same age. The chief enlargement, as the heart lay in situ, was to the left and slightly downwards. Further examination showed a large ovoid tumour in the lateral wall of the left ventricle, displacing the cardiac chambers to the right and upwards. The cavity of the left ventricle was dilated, but not to a marked degree. The tumour comprised by far the greater bulk and weight of the heart, and measured 3 in. by 2½ in. on section. It was firm, pale, almost white and fibrous-looking, and the cut surface showed, distinctly, coarse fasciculation throughout. A thinned-out but complete layer of ventricular muscle intervened between the tumour and both endocardial and epicardial surfaces, but this was so thin that the pallor of the underlying tumour tissue could be seen from both surfaces, especially the epicardial. Although clearly demarcated from the cardiac muscle, the tumour had no definite capsule and its contour was slightly irregular. The gross appearance was very like that of a fibroma.

Microscopic Examination.

The tumour was composed throughout of interlacing bundles, some seen in cross section, others in tangential or intermediate planes of section. (Fig. 1.) Each bundle was composed of striated muscle of the cardiac type, and within the bundle each small group of muscle-fibres was separated, from its neighbours by numerous coarse interlacing fibres of collagenous connective tissue. Most of the connective tissue fibres ran in the same direction as the muscle-fibres of the bundle, but a considerable number branched off to run obliquely across the muscle-fibres and interlace with neighbouring longitudinal fibres of connective tissue. Thus each bundle was composed of muscle-fibres and connective tissue running in the same direction, but with the fibres of the latter also anastomosing across the intervening muscle and so bracing the whole bundle together. The greater actual bulk was connective tissue. To this, however, very few indeed of the nuclei present were related, and such fibroblastic nuclei, small, elongated, narrow, and darkly staining, were easily differentiated from the others. The remaining nuclei were all muscle nuclei, most of them well-differentiated and closely

resembling the adult cardiac muscle-cell nucleus. A minority were undifferentiated myoblastic nuclei. The fibres in which the muscle nuclei lay showed in most cases distinct regular cross and longitudinal striation (iron haematoxylin; phosphotungstic acid haematoxylin; haemalum and picrofuchsin). (Fig. 2.) It was sometimes possible to identify alternate light and dark bands of cross striation. Here and there, however, small specially cellular areas were encountered. It was mainly in such areas that the nuclei were larger, sometimes much larger, oval or rounded, and evidently myoblastic. The cytoplasm was of irregular form and extent, being sometimes syncytial and vacuolated. It stained as did the cytoplasm of the obvious muscle with the various stains used, but only here and there did it show limited patches of regular striation. Elsewhere it was clear, or contained granules staining similarly to the constituent granules of the regular cross striations, but either completely without arrangement or forming irregular and incomplete lines of dots.

The vessels of the tumour were well-formed. No other types of tissue were discoverable in it. There was no appreciable difference between the appearance at the centre and that at the periphery of the tumour, and the ratio of muscle to connective tissue appeared roughly uniform throughout.

Commentary.

With the presence of this tumour in the heart the child was living on the edge of a precipice, and any sudden exertion or strain would be sufficient to bring about a catastrophe. Nearly all the cases reported by Uehlinger³ occurred in children, probably because the patient is seldom spared until adult life. However, the case reported by Bradley and Maxwell,¹ a primary rhabdomyosarcoma of the heart, occurred in an adult, 62 years of age. As it happened, the precipitating factor in this case was the bout of crying, brought on by the slight injury received. The extra strain put on the heart, with the increase in blood pressure, was enough to overtax an organ already burdened by the presence of this neoplasm. It is interesting to note that at no time previously had the neoplasm given any signs of its presence, although it is not unreasonable to suppose that the child must have indulged in bouts of crying equally as vigorous as this one during its three months of life. None of the signs referable to the heart which have been reported in neoplasms of the heart (Perlstein²)—e.g., oedema, cyanosis, hæmoptysis, or ascites—were present in this case.

While the naked-eye fibrous texture of this tumour was explained on microscopic examination by the presence of an abundance of connective tissue, it was also evident that the connective tissue was not the active cellular element but was rather an abundant framework supporting the essential element of striated muscle. This muscle, while for the most part well differentiated, was here and there myoblastic, and the conclusion that the tumour is a solitary congenital rhabdomyoma of the heart seems irresistible.

In two respects, however, the structure described differs rather strikingly from the usual description of rhabdomyomata of the heart.

1. The structure usually found is more myoblastic and less differentiated than that seen here. There is also a much more extensive vacuolation and an even greater cellularity. This striking vacuolation has been described as invariable (Wolbach⁴ and others). While single oil-immersion fields can be found in the present tumour presenting in parts the usual myoblastic and vacuolated appearances, they are few and far between.

2. Accompanying connective tissue seems to be more abundant here than ordinarily, and the tumour is therefore firmer and paler than is usually found.

We wish to tender our acknowledgments to Mr. W. Nelson for taking the microphotographs here reproduced.

Clinical and Laboratory Notes.

A CASE OF MULTIPLE CONGENITAL SKELETAL DEFORMITIES

CAUSING CONGENITAL SCOLIOSIS.

By H. L. REES, M.R.C.S. ENG.,

HOUSE SURGEON, RADCLIFFE INFIRMARY, OXFORD; LATE
HOUSE SURGEON, BELGRAVE HOSPITAL FOR
CHILDREN.

Cases of congenital scoliosis occur in otherwise normal infants, and are due to maldevelopment of the vertebrae or of the ribs, and are associated with elevation of the scapula, outgrowing hip and changes in the lateral thoracic wall. The following is a brief description of such a case.

A girl, aged 6, was noticed to have a mole on her back at birth, which was normal, and six months later her mother observed that her back was crooked. This condition was treated by a leather jacket worn during the day. She is a bright intelligent active child, with a marked scoliosis in the thoracic region, the convexity being towards the left, the greatest deviation from the normal being at the level of the sixth thoracic vertebra, where there is a spina bifida occulta associated with a hairy mole (Fig. 1). There is compensatory scoliosis in the lumbar and to a minor degree in the cervical regions, and marked kyphosis at the level of the ninth and tenth thoracic vertebra with compensatory lordosis in the lumbar region. Marked posterior bulging of the ribs is evident on the right side with but little compensatory bulging of the left rib anteriorly, while the left side of the chest is half an inch larger in circumference than the right at the level of the angle of the scapula. There is very little movement in the thoracic vertebrae, even when the patient is suspended by her arms from a horizontal bar, but full movement is possible in the lumbar and cervical regions.

The head is held with about five degrees lateral flexion; there are no ocular symptoms. A loose fold of skin stretches from a point posteriorly to the right mastoid process to the right acromion process. The right shoulder is held at a higher level than the left, the right scapula being rotated so that the angle lies only half an inch from the spinous processes as compared with a distance of two and a half inches on the left side.

The pelvis is very slightly tilted, the left gluteal fold being slightly higher than the right, and being more marked. The only difference in the legs is a slight genu valgum on the left side. A pelvic examination has not been made.

X ray examination shows the causes of the scoliosis which is due to non-fusion of the lateral halves of the body of the second thoracic vertebra, the right half being displaced laterally and articulating with the second rib, which after fusion with the third rib for a short distance becomes bifid at the angle, and also to suppression of the right half of the eleventh thoracic vertebra. There is also non-union of the lateral halves of the sixth thoracic vertebra—the site of the spina bifida occulta—and of the ninth and tenth thoracic vertebra. The eleventh and twelfth ribs are absent on the right side. A tracing from the radiogram is shown in Fig. 2. A plaster jacket has been made for the patient to lie in whilst at rest, in order to check the increasing deformity and in the hope of partially correcting it by inserting suitable padding. A leather spinal support is worn during the day. She has been given massage for the fold of skin of the neck and scoliosis exercises, but it

FIG. 1.

Photograph showing site of spina bifida occulta and hairy mole.

is doubtful if the latter will have any beneficial effect on the deformity.

The striking features of the case are the number of

FIG. 2.

Tracing from radiogram.

and in order to prevent the increase of the deformity during the active days of childhood.

I am indebted to Mr. C. P. G. Wakeley, under whose care this case was treated at the Belgrave Hospital for Children, for permission to publish these notes.

A. NEW TREATMENT FOR ARTERIAL CALCIFICATION.

By DR. VLAD. MLADJOWSKY,

PROFESSOR AND CHIEF OF THE INSTITUTE OF BALNEOLOGY AND PHYSICAL THERAPY, KARL UNIVERSITY, PRAGUE.

THE usual routine treatment and therapy for arterio-sclerotic patients always seemed to me so inadequate that I have employed a course of treatment not generally known which has proved so successful that I am desirous of placing this communication before my British confrères. Arterio-sclerosis is a physiological accompaniment of old age and may be hereditary. The commonest causes are mental excitement and a diet too rich in proteins, combined with insufficient physical exercise, especially in middle age. Contributory causes are nicotine, alcohol, and infections. Severe physical exertion with an insufficiently nutritive diet may lead to the same result. Where there is deficient toxin elimination by the intestines and skin the kidneys become overburdened and nephrosclerosis may occur. The well-known changes in the intima and media of the arteries cannot account for the whole of the clinical picture. Many authors report that certain drugs, such as

iodine and silica, mitigate the troublesome subjective symptoms (vertigo, headaches, insomnia, angina pectoris), but the same auscultatory signs remain. This coincides with my own experience. All these symptoms cannot be wholly due to high blood pressure, for they frequently disappear before the blood pressure has decreased, which proves that the pathologico-anatomical changes detectable by auscultation and frequently by X rays may exist without any subjective disturbances and that there must be other causes which require special remedial treatment.

It is probably correct to regard certain symptoms of arterio-sclerosis as splanchnic crises due to calcification of the nutritive vessels. If the demands on it are moderate the blood stream flowing through the narrowed arteries suffices, but otherwise its insufficiency causes crises. The clinical picture is obviously highly complicated, presenting many points of attack for therapy, and though there is little hope that the anatomically changed arteries will return to normal conditions there are prophylactic possibilities and the probability of retarding progress and of rendering the patient's condition endurable.

The skin of arterio-sclerotics, particularly the skin of the face and extremities, supplies an index to many of the symptoms. The extremities are cold and livid as a result of derangement of the heat regulation, while the hue of the nose is typical of the aged face. Small arteries show on the nasal alae and cheeks, and the skin becomes inelastic, furrowed, and dry. Another type, most frequently occurring in the obese and usually of very long standing, is the markedly pale, pasty, dry skin. These individuals may be subject to the same disturbances of heat regulation as the first type and attacks of cardiac spasm are frequently ushered in by the appearance of redness in Head's "cardiac region." All these symptoms are, no doubt, due to the same causes as the arterial calcification and partly to disturbances of internal secretion.

By an extensive series of tests made in the department of balneology and physical therapy at Prague University we were able to demonstrate that after thermal and mechanical (and also electro-therapeutic) treatment, blood pressure was raised very temporarily and by no more than the ordinary daily variations, and fell again when the skin reaction set in. There is no danger in the increase of blood pressure as is proved by our treatment of several thousand cases of arterial calcification, without a single hæmorrhage. The skin as well as the arterial calcification can be influenced hydropathically. The patient must react normally, and if he fails to do so the process must immediately be modified to suit his condition. The heat regulation usually improves after this treatment. It is possible by certain procedures to provoke hyperæmia or anæmia of the skin and the general circulation and thus the heart will be greatly relieved. This is often of more value than cardiac and vascular medication. Hydrotherapy is also capable of affecting the internal organs via the skin. The method described forms the basis of the treatment and can be altered to meet individual cases.

Technique.

The patient is well brushed in a warm (35°-38° C.) half bath for 10-20 minutes and then receives a good douching with a fan-shaped douche from a distance of 8-7 ft., at first for two to three minutes with water at 35° C., then with water at 25° C. for one to two minutes. These douches are repeated two or three times. At first they are usually applied to the back and lower extremities and later over the whole body. The patient is thoroughly dried, well wrapped up, and then allowed to lie down for at least half an hour.

Some patients react badly to the heart stimulation; it deranges the body heat regulation; they tend to shiver; the isothermic water seems cold, and after the procedure they cannot regain warmth; and skin reaction does not take place. For these we begin with half baths, usually at 38° C. for not more than 10 minutes; the brushing must be energetic. We decided on 38°-40° C. for the douches, after which the patient must be well rubbed until the skin becomes red and the feeling of cold vanishes.

Should the patient be very delicate or suffer from hypotension, myocarditis, or cardiac debility, artificial sunlight

is applied instead of the baths, and we only resort to hydrotherapy when the condition has improved.

This treatment has given highly beneficial results in several thousand cases. The subjective symptoms disappear, the blood pressure decreases, and the skin assumes its normal appearance. The auscultatory symptoms and X ray picture, however, mostly remain unchanged. Painful sensations in the cardiac region are treated by anionisation. If the patient suffers from spasms we bring into use the "tonisator," an apparatus devised by Dr. Ebel of Vienna by which a faradic current is varied in intensity and frequency by means of a clockwork mechanism without producing any discomfort.

Drug Treatment.

Silica has long been used in French therapy and a beneficial effect on arterial calcification claimed in cases of tuberculosis. Intravenous injection brings with it the danger that some of the solution may find its way into the cellular tissues and set up painful reaction. I therefore determined to try silica given by the mouth in colloidal form. Many authors assert that silica deficiency in the organism is due to bad intestinal resorption. To prove this I decided to combine the silica with an extract of *Drosera*—the common *Drosera rotundifolia*. Modern pharmacology gives us little information about this plant, but since it is an insectivorous plant it must contain ferments which not only digest proteins but also chitin. The researches of Stocklase have shown that the ferment of the *Drosera* is a far more efficient proteolytic agent than pepsin; and that *Drosera* possesses a keratolytic ferment and an iodoxydase. The extract had therefore to be prepared in such a manner that all the ferments remained intact. For convenience of administration the drugs were prepared in tablet form under the name of "Drosil." I found that its action was surprisingly efficient in overcoming the subjective troubles of arterio-sclerosis (vertigo, confusion, insomnia, cardiac oppression) and in the alleviation of the symptoms of cardiac debility such as dyspnoea, articular oedema, and hypostasis. In cases of hypertonia a slow but lasting improvement took place. Two of the tablets are taken thrice daily; they may be dissolved in hot water. The treatment lasts for four or five weeks and during this period the patient's condition usually shows a marked improvement. An interval should follow until the old symptoms reappear; this interval may last for weeks or months.

It is advisable to combine this therapy with hydrotherapy and then to continue the hydrotherapy. The diet should be light with little protein. Open-air exercise is helpful. It may be that the *Drosera* ferments assist the adsorption of the silica and so supply the silica deficiency in the organism—a substitution therapy. There is also a possibility that the silica which is resorbed in a form convenient to the organism may act as a catalyst, effective as a remedy for harmful effects, and at the same time as a retardative of colloidal changes. It is valuable for the musculature and especially the heart muscle. Stocklase recently discovered a lipolytic ferment in the *Drosera*, and I am experimenting with this and with a combination of silica, *Drosera*, and extracts of the thyroid and sexual glands.

SHROPSHIRE ORTHOPÆDIC HOSPITAL.—Last year this institution treated a total of 4720 patients and, after spending £48,541, had a credit balance of £30. The hospital, which is at Oswestry, has 33 clinics scattered over eight counties. A cinema has been installed, and films are shown on two nights a week to the patients and on another to the staff and those who are being trained at the Derwen Cripples' Training College, which is close to the hospital. The after-care scheme now embraces an almost equal proportion of preventive work. The temporary buildings erected 16 years ago are very costly to keep in repair, and it is proposed to begin the work of reconstruction by providing a new nurses' home.

Reviews and Notices of Books.

ANATOMY.

Lehrbuch der Systematischen Anatomie. By Prof. Dr. JULIUS TANDLER, Director of the First Anatomical Institute, Vienna. Vols. I.-IV. Leipzig: F. O. W. Vogel. 1926-29.

IN 1912 Prof. Tandler, of the First Anatomical Institute in Vienna, began to write his magnum opus, but the war and its after-effects interfered with this work as with that of many others, and it was not before the latter part of last year that the last of his four volumes appeared. The standing of the author, and his unimpeachable authority when writing on his subject, make the completion of this work a matter of considerable interest throughout the anatomical world. It will rank among the leading text-books in the German tongue.

The first volume deals with the skeleton, joints, and muscles, the second with the viscera, the third with the circulatory system, while the last and largest volume is concerned with the central nervous system, nerves, and special sense organs. The accounts given of all these parts are, of course, full and accurate, but the outstanding feature which impresses one throughout is the simplicity and clearness of description. This is particularly apparent in the consideration of the central nervous system, where the mental picture called up is hardly bettered in any text-book with which we are acquainted. The almost complete absence of embryological reference, except as the necessary foundation of the nervous system, is the more striking because of Prof. Tandler's eminence in that branch of anatomy. In the earlier advertisements of the book it was stated that a final part was planned including, among other matters, a short account of development, but the author makes no mention of this in the foreword to his fourth volume. The illustrations, of which there are more than 1200 in all, are beautiful as well as useful.

Prof. Tandler deserves the congratulations as well as the thanks of his colleagues in all countries for this great book, which is weighty without being heavy, and is stamped with his personality in a way which distinguishes it from the compilations which now form the basis of many modern text-books.

A Text-book of Anatomy and Physiology. Third edition. By JESSE F. WILLIAMS, M.D., Professor of Physical Education, Teachers' College, Columbia University, New York City. London: W. B. Saunders Company. 1929. Pp. 578. 12s. 6d.

THIS book, evidently in demand, is intended for students of the practical arts—to use its author's words—such arts comprising nursing, physical education, physiotherapy, occupational therapy, and household crafts. We imagine that it is rather intended as an aid and stimulus to the teacher than for the immediate study of the students themselves, but in any case it is one of the best books of its kind that we have seen. This edition has been revised in many ways, and a large glossary has been added. There is not, perhaps, the same demand for books of this class in England. It is not full enough, of course, for students of medicine as their only text-book, but many of these students would learn a good deal if they studied it after they have done their intermediate courses. It is very well illustrated and produced.

PATHFINDERS IN MEDICINE.

Second edition. By VICTOR ROBINSON, M.D. New York: Medical Life Press. 1929. Pp. 810. \$10.0.

Dr. Victor Robinson, in this second edition of his work, has much increased both its scope and value. The volume now consists of a series of 30 essays

written during the past 20 years, which have been published separately in various appropriate journals or have found their way into the archives of medical societies, and their collation adds to their individual merits and makes up a useful book of reference. The pathfinders, whose work as pioneers in medicine is described, are as follows: Galen, Aretaeus, *Rhazes, Paracelsus, Serretus, *Vesalius, Paré, *Descartes, *Malpighi, John Hunter, Edward Jenner, Henry Cavendish, Schiele, Berzelius, *S. Guthrie, Laennec, *Purkinje, Schleiden-Schwann, *Hensle, Darwin, J. Y. Simpson, *Duchenne, *Bernard, *Hebra, Semmelweis, *Elizabeth Blackwell, *Pasteur, *Koch, *Metchnikoff, and *Pavlov. The names in this distinctly capricious list which are marked with an asterisk are the pathfinders whose lives comprised the first edition of the book, the remaining 15 names denote the subjects added for the purpose of this issue. All the essays are written in an extremely readable fashion, many of them are adequately illustrated, and the material often owes both its detail and its accuracy to the assiduous manner in which Dr. Robinson has approached relatives, descendants, and recognised authorities for information and criticism. This is particularly obvious in the longest article, that devoted to the life of Hensle; it includes four portraits of Hensle himself and portraits of his wife, mother, sister, and daughter, and several facsimiles of his handwriting. The chapter would make a small book in itself and will be read with interest by those who know no German, for Hensle is not frequently brought to the attention of English readers.

This is a handy work of reference and in many cases the biographies, though individually brief, will be found to need little supplement in essentials from larger lives of the various pathfinders.

BIRTH CONTROL ON TRIAL.

By LELLA SECOR FLORENCE. Foreword by Sir HUMPHRY ROLLESTON, Bt., K.C.B. Introduction by F. H. A. MARSHALL, F.R.S. London: George Allen and Unwin, Ltd. 1930. Pp. 160. 5s.

THIS book provides a detailed and disinterested survey of contemporary contraceptive methods. Mrs. Florence has followed up, with a scrupulous perseverance that deserves much praise, the first 300 women who attended the Cambridge Women's Welfare Centre for advice on birth control. Of these 300 patients, Mrs. Florence failed to trace only 25. A further 26, for one reason or another, were never given advice on birth control. Records are therefore available of 247 women. Of these women, 75 found that the contraceptive method taught them failed in one way or another. Three of this number experienced two successive failures, with the result that 78 pregnancies resulted. Another 80 patients for various reasons gave up the method that they had been instructed to use at the clinic. Out of 247 patients, therefore, no less than 155 found that the pessary or the sheath was unsatisfactory. These cases are analysed with some care in the book, which should prove of great value to medical men who want an impartial account of the efficacy and practicability of the various methods of birth prevention.

Of the many interesting points brought out by the survey, three deserve notice. The first is that the experience of the Cambridge clinic caused the medical officers to place more and more reliance on the sheath as the most dependable method for those couples who do not find it esthetically objectionable and in which the husband can be relied upon to use it. The sheath has received an undue amount of condemnation by writers on contraception. The Cambridge clinic uses with success an article that costs sixpence. These are frequently employed for three or four months, and a case is on record of a man who used his without mishap for three years consecutively. A second point which the author frequently stresses throughout the book is the need for further research. From the chapter dealing with successful

cases, it is obvious that the clinic in Cambridge performs a highly valuable function. To argue from the high proportion of failures that this clinic, and the other birth control clinics, are useless would reveal a lack of understanding of the needs of working-class women, many of whom are grateful for knowledge which, if it fails to prevent childbirth, at any rate enables them to prolong the intervals between childbirths. The imperfections of existing methods should move us not to despair, but to seek to find better methods. A third point that deserves notice is the prevalence and unreliability of *coitus interruptus*. Of 265 patients, 118 had practised this method before coming to the clinic, and in these cases it had failed to the extent that there resulted no less than 400 unwanted pregnancies.

Though the numbers on which this study is based are small, the follow-up has been unusually thorough. The author writes with an impartiality and restraint unusual among advocates of birth control.

INFECTIOUS DISEASES.

Acute Infectious Diseases. A Handbook for Practitioners and Students. Second edition, revised and enlarged. By J. D. ROLLESTON, M.D. Ox., M.R.C.P. Lond., Medical Superintendent, Western Hospital, S.W. London: William Heinemann (Medical Books), Ltd. 1929. Pp. 419. 15s.

THE first edition of this excellent book which appeared over four and a half years ago was based on the author's personal experience and on a study of the literature of the commoner acute infectious diseases. In this second edition new work has been incorporated, the principal additions and alterations being in the chapters on diphtheria, typhoid fever, scarlet fever, measles, and vaccinia. References to the literature of the various diseases has been brought well up to date. Immunisation against diphtheria and scarlet fever, and also the attempts to immunise young children against measles, by means of convalescent serum and whole blood, including virulent whole blood, are well described. The measles problem is undoubtedly a difficult one in large cities where hospital accommodation is inadequate; immunisation may well help to reduce the high mortality from measles associated with overcrowding in congested slum areas. Since patients suffering from influenza, parvular fever, anterior poliomyelitis, and encephalitis lethargica are nowadays admitted to many fever hospitals, chapters on these diseases might usefully have been added. Dr. Rolleston's views on treatment are of interest. Many physicians still adopt the practice of giving alcoholic stimulants in acute infectious fevers. Dr. Rolleston gave up this practice many years ago, and holds that there is no justification for the routine administration of alcohol even in diphtheria. No illustrations are provided. The average student undoubtedly learns much from good pictures of rashes, while even temperature charts help him to remember the characteristic course of the various exanthemata. Practitioners who have already a working knowledge of the infectious diseases need neither of these aids, and will find here just what they require, as well as numerous references to original communications.

Infectious Diseases for Nurses. By EUSTACE THORP, M.B., Ch.B., D.P.H., Deputy Medical Officer of Health, Sunderland. London: Baillière, Tindall and Cox. 1929. Pp. 131. 5s.

THIS little book is primarily designed for nurses and is based on a series of lectures to them. Dr. Thorp obviously agrees with the teaching of the best authorities on fevers, and the book contains valuable information put in familiar language. He deals with all the common infectious diseases and, in addition, provides brief chapters on such diseases as undulant fever; encephalitis lethargica; anterior poliomyelitis; tuberculosis, including tuberculous

meningitis and surgical tuberculosis, &c.; ophthalmia neonatorum; puerperal fever and venereal disease. A good account of bed isolation is included with detailed instructions for barrier nursing. Dr. Thorp divides the stages of laryngeal diphtheria in two ways, giving first quite a satisfactory classification and then a second one—which he prefers; this duplication is likely to confuse nurses. On the whole, however, this is a good book and should become popular.

GYNECOLOGY.

Fourth edition. By BROOKE M. ANSPACH, M.D., Professor of Gynecology, Jefferson Medical College, Philadelphia. London: J. B. Lippincott Company. 1929. Pp. 752. 42s.

THIS is now one of the most popular American text-books on gynecology, having reached four editions in eight years. A certain amount of new matter has been added but no great changes have been made in this edition. Unlike the authors of most recent American text-books, Prof. Anspach does not dismiss the radical operation for carcinoma of the cervix as an obsolete operation. It is described in detail, though it is definitely held to be inferior to radium in the treatment of carcinoma of the cervix. It is curious that the results obtained with radium at such centres as Stockholm and Paris are not mentioned even among the references to original publications which round off each chapter. Of particular interest are the accounts of recent work on sterility and of the uses of electricity in gynecology.

LABORATORY METHODS OF THE UNITED STATES ARMY.

Edited by CHARLES F. CRAIG, M.D.; Colonel: Medical Corps, United States Army. Philadelphia, Lea and Febiger. 1929. Pp. 696. \$3.50.

THIS book is written by laboratory workers for their kind, being designed for the guidance of workers in the laboratories of the United States Army Medical Corps. It contains descriptions of all the procedures used in these laboratories, but no details about interpretation of findings; the descriptions are clear and concise, and the editor has had the good judgment to include in every instance an account of only one well-tried procedure for one particular purpose. In so doing he has made a step towards the much-needed standardisation of laboratory procedures. Being designed for an Army Service, the book deals not only with the ordinary laboratory procedures of use in general medicine, but also with the examination of water, alcohol, foodstuffs, and also of veterinary specimens. These sections will make the book particularly useful to the isolated laboratory worker, who is only occasionally called upon to deal with work of this sort.

THE SOYA BEAN AND THE NEW SOYA FLOUR.

By C. J. FERRÉE. Revised translation from the Dutch by C. J. FERRÉE and J. T. TASSAUD. London: William Heinemann (Medical Books), Ltd. 1929. Pp. 79. 6s.

A FULL account is here given of the Soya bean, its history, cultivation, and nutritive properties. As one reads one feels that such a nonpareil among vegetables has indeed suffered neglect for too long, but the cause of this neglect is to be found in the extreme difficulty of rendering it palatable for Western consumption. The object of the book reveals itself in the statement that this difficulty of unpalatability has been overcome by means of a secret process discovered by a Hungarian, Dr. Laszlo Bercezzler. There is no doubt that the Soya bean has extraordinary nutritive properties, which if they could be applied to supplement dietaries in Europe and in Asia, particularly in British India, might convey great benefit. This book should not, however, be mistaken for a scientific manual on the subject.

ULTRA-VIOLET LIGHT AND VITAMIN D IN NUTRITION.

By KATHARINE BLUNT, President of Connecticut College; formerly Chairman of the Department of Home Economics, University of Chicago; and RUTH COWAN, Instructor in Home Economics in the University of Chicago. Chicago: University of Chicago Press. 1930. Pp. 229. 11s. 6d.

THE object of the book is to place at the disposal of those whom it should chiefly concern—i.e., physicians, dentists, teachers of nutrition, and parents—a general survey of the remarkable progress which has recently been made in our knowledge of vitamin D and ultra-violet light and their relation to the calcium and phosphorus metabolism of the body. It covers the field well and most accurately, the exposition being clear and not too technical for the first three categories of persons named, but for the average parent it would make difficult reading.

The book is naturally built up largely on Transatlantic work, and to British readers the occasional lapses into colloquial style will be unwelcome. However, fair credit is given to researches made in Europe, and in general the handbook can be warmly recommended.

JOURNALS.

INDIAN JOURNAL OF MEDICAL RESEARCH.—The issue of January, 1930, contains 34 papers covering a wide range of research work in India. T. A. Hughes and D. L. Shrivastava contribute two papers on the enlarged malarial spleen, and J. A. Sinton, S. Smith, and D. Pottinger record the therapeutic effects of plasmoquine and quinine in malaria. In a separate publication Sinton details his observations on the parosan and dimeplasmine treatment of the same disease. The dietetic deficiencies receive much attention. R. McCarrison compares the dietetic value of whole wheat and white bread; the latter is not recommended as a staple article of diet owing to its lower nutritive value and deficient content in vitamin B. Another paper by the same author deals with the effects on the tracheal mucous membrane and on the thyroid gland of food poor in vitamin A. C. Newcomb investigated the water content of the myocardium in beri-beri columbarum, and found that the enlargement of the heart was not explained by water retention. D. C. Wilson and her colleagues contribute two papers on osteomalacia (late rickets) in India, the first dealing with the blood picture and the second with aetiological considerations. A consistent lack of vitamin D and deficient sunlight were the chief factors implicated, but an excess of cereals in the diet contributed to some degree. The incidence of rickets and dental caries in school-children forms the basis of another paper. L. Wills and M. M. Mehta issue a preliminary report on pernicious anaemia of pregnancy; they found the gastric secretion of hydrochloric acid practically normal, the indirect van den Bergh readings low, and the blood picture megalocytic in type. The significance of diets poor in vitamins A and C are discussed. A. C. Ukil contribute two papers on tuberculosis in India. The first deals with its epidemiological and pathological aspects, the second with the rôle of secondary bacterial infection in phthisis. In kala-azar, L. E. Napier and C. R. Das Gupta demonstrate the value of a provocative injection of pentavalent antimony in diagnosis, while elsewhere R. B. Lloyd, L. E. Napier, and G. C. Mitra show that this disease in the absence of syphilis does not give rise to a positive Wassermann reaction. W. J. Webster and G. D. Chitre describe a simple method of rearing laboratory-bred rat fleas and also recorded the successful transmission of plague by *X. brasiliensis*. Several other important entomological contributions are made, the most striking being the demonstration by H. E. Shortt and his collaborators of the presence of *Leishmania donovani* in wild *Phlebotomus argentipes*. The issue closes with an interim report on the bacteriophage inquiry conducted under the auspices of the Indian Research Fund Association.

THE LANCET.

LONDON: SATURDAY, APRIL 26, 1930.

HOSPITAL POLICY.

A SUPPLEMENT to last week's issue of the *British Medical Journal* contains a detailed account of the revised hospital policy of the British Medical Association—that is to say, that the document provides an orderly review of the social changes in recent years as reflected generally in hospital management and conduct. Hence it makes informing reading alike for medical staffs of hospitals, private practitioners, the patients, and the public. The views of the Association with regard to hospital accommodation are set out with typical schemes for the organisation of two main types of institution—namely, the voluntary and the municipal, or those which now have come under the authority of County Councils through the recent Local Government Act. In both cases the Association is concerned especially to see that certain fundamental conditions are met, such as the limitation of hospital accommodation to those patients where medical service in the best interests of the patient can be given only in an institution, and an arrangement for the medical staffing in accordance with principles approved by the medical profession.

A further condition of right hospital policy is also indicated in the opinion given that the normal method for the admission of patients should be on the recommendation of a medical practitioner. Of recent years this right way of filling the beds has been more generally adopted, and the system by which subscribers, in recognition of their generosity, could nominate candidates for reception in crowded institutions has fallen into discredit. This system was always looked at askance by those who had the best interests of the voluntary hospitals at heart, but it was the common view of those who had the financial management of the charities in their hands that its maintenance was valuable for opening the public purse, and in deference to this business attitude it was persevered in till lately. But under the abuse of hospital letters, especially at certain of the metropolitan hospitals, the practitioner was much discouraged from sending patients for hospital treatment in those earlier stages when that treatment would have been most beneficial; and when the patient was so ill that entrance to the hospital could hardly be refused, the practitioner felt that it was the desperate need of the subject, and not any prevision of his own, that had secured, and possibly secured too late, the ministrations that were needed. This situation should no longer arise, and probably the cases that find their way into the wards in this miserable manner are now much fewer, while medical service under the National Insurance Act provides, as a part of the routine performance of the practitioner's duty, the recommendation of cases fitted in his judgment for hospital treatment to authorities who, on their side, recognise that to welcome such patients as far as possible is to give development to one of the most important implications of the Act. As we all know, the waiting-lists at most of our general hospitals are pathetically long, and the main reason

for this is that a vastly larger number of persons, qualified by sickness and suffering for institutional care, are detected than was formerly the case. These persons constitute the sad crowd with which the new municipal hospitals will have to deal in part, as and when they are able to meet the responsibility, while the number of beds which we may soon see opened will enable some method of classification to be arrived at by which certain centres will be selected for the relief of particular groups of cases. Such a method should provide great opportunities for teaching, when this mine of material can be fruitfully worked through the offices of capable teachers, and in this way a further ideal can be realised—which also is emphasised in the statement of the Association—that as far as possible all hospitals should be available for purposes of medical education.

The essence of the conduct of voluntary hospitals has been the independence inherent in their management. This has been insisted upon over and over again in these columns, and the arguments have been reiterated to show that a system under which the charities manage their own affairs has worked to the advantage of the public, while fostering the advancement of medical science. It was assumed that this independence was a corollary of the fact that the benefits bestowed by the voluntary hospital were gratuitous and that the medical staffs were unpaid. An alteration in professional opinion must be recorded here, as the Association recognises when outlining a dual interpretation of the voluntary principle. The purely charitable side, it is stated, should be continued, wherein the whole cost of the maintenance of free patients is met by the gratuitous contributions received by the hospital, on whose behalf the services of the visiting medical staffs are given gratuitously; but it is added that patients, other than free patients, may be received for treatment at voluntary hospitals and that for them payment should be accepted by the hospital either from the patients themselves or, on their behalf, from the authority or body referring them to the hospital, and that on account of their treatment suitable methods of remuneration of the visiting medical staff should be arranged. This is a succinct statement of what is now a widely held professional view, but in the consequent pecuniary arrangements there are factors to be considered which will render difficult that desirable "medical staffing in accordance with principles approved by the medical profession." This is the place where the claims of the voluntary and the municipal hospitals may be opposed in a manner calling for delicate adjustment.

POLIO-ENCEPHALITIS SO CALLED.

A FEATURE of the Registrar-General's return of infectious diseases for many weeks past has been a high proportion of cases of polio-encephalitis relative to the number of cases of poliomyelitis. Three weeks ago, and again this week, the number classified as polio-encephalitis was actually higher than the number under the heading of poliomyelitis. We think it is right that these figures should be submitted to some scrutiny. Apart from certain cases in which the bulb or pons is involved, true polio-encephalitis is unquestionably a very rare disease, even at times when the poliomyelitis infection is prevalent. WICKMAN, in the great Swedish epidemic of 1905, saw no instance of polio-encephalitis; KRAUSE, in the Westphalian epidemic of 1909, saw only one case; ZAPPERT, in a collection of 555 cases of poliomyelitis, found only five cases which he regarded as polio-

encephalitis; PEABODY and DRAPER, among their own 183 cases, did not find a single typical case of polio-encephalitis; and SÖRENSEN, among nearly 100 cases in Copenhagen, saw no case which he could confidently describe as polio-encephalitis. It has been common, however, in this country, following the lead given by STRÜMPPELL in Germany in 1885, to ascribe a large proportion of cases of hemiplegia in infants to encephalitis resulting from infection by the virus of poliomyelitis. These are cases in which, after a short period of malaise and pyrexia, convulsions occur and are followed by hemiplegia. The illness, like poliomyelitis, usually affects children within the first three years of life, and it is apt to occur during or shortly after one of the acute specific fevers. It is to be assumed that most of the cases included as "polio-encephalitis" in the official returns are of this nature.

These cases of infantile cerebral palsy, as was pointed out long ago by G. F. STILL, show neither the seasonal incidence nor the epidemic occurrence which are features of acute anterior poliomyelitis. Whereas in a very large proportion of the cases of the latter disease in this country the onset occurs during the autumn months, infantile hemiplegia appears to come on with equal frequency at all times of the year. Many epidemics of poliomyelitis have now occurred in different parts of the world, but no special prevalence of infantile hemiplegia has been described in association with them. A significant fact to which attention was drawn by STILL, and which has recently been proved anew by FAIRBROTHER and HURST, is that, in the experimental production of acute anterior poliomyelitis in monkeys, the intracerebral inoculation of the virus does not result in spastic paralysis of the cerebral type, but in flaccid (i.e., spinal) paralysis of the lower limbs, with the lesions of acute anterior poliomyelitis in the spinal cord. It is evident, therefore, that even in conditions which would seem especially to favour the occurrence of a cerebral paralysis the virus of poliomyelitis maintains its affinity for the spinal cord and does not produce the spastic paralysis which is seen clinically in infantile hemiplegia. There seems thus to be no sufficient ground for regarding infantile hemiplegia, coming on in association with a febrile illness, as having any close kinship with the more common spinal infantile paralysis.

At the present time there is another group of cases which is likely to swell the number of those grouped under the heading "polio-encephalitis." These are cases of encephalitis occurring in association with one of the specific fevers, such as measles, or even without any such association. Such cases of acute disseminated encephalitis seem to have been much more common during the last two or three years than formerly. The pathological changes found in the brain in these cases differ in many important particulars from those produced by the virus of poliomyelitis, and it is therefore certain that these cases are distinct from polio-encephalitis. It will be apparent that all statistics relating to polio-encephalitis must for various reasons be fallacious, and that they are likely to remain so as long as we are devoid of any specific test for recognising infection by the poliomyelitis virus. Whether any useful purpose is served by having a separate group for "polio-encephalitis" in the official returns seems doubtful. It will also be apparent that the diagnosis of polio-encephalitis is one which should be made at all times with reserve, and which, as applied to disease of the cerebral hemispheres, is hardly plausible except at times when poliomyelitis is rife.

PSYCHIATRIC REFORM.

Dr. MAPOTHER's impressions of psychiatry in America, which we published last week, are timely seeing that the Mental Treatment Bill has not yet passed through all its stages. They will shock those who think we have nothing to learn from other countries and who are satisfied that the eighteenth and early nineteenth century reforms, in which England took a large part, so settled the principles of treatment of the insane that for ever in this country its abuses and corruptions are removed. In America ample money has been available for the endowment of missionaries on mental hygiene, and the Commonwealth Fund has acted on the principle that private charity is best directed towards financing hopeful experiments, withdrawing its support when the experiments have proved so successful that the work ought to become a part of the national duty. On these terms a child-guidance clinic has recently been started in London, and the British psychiatrists appointed to it visited America to study American methods. The International Congress of Mental Hygiene to be held in Washington next month will take many of our own mental specialists across the Atlantic, and there is constant interchange of medical and lay psychological workers between the two countries for brief periods of training. The chief point that emerges from Dr. MAPOTHER's survey is the remarkable freedom of American psychiatrists from legal interference. America has learnt to trust her experts in a way that England has not. She has also learnt to subsidise efforts to secure mental health, both from State funds and private munificence. The governor and legislature in most progressive American States are content to limit their province in the realm of mental disease to deciding how much money they can afford for new ventures. Procedure varies from State to State, but the permanent Commissioner, if a psychiatrist with institutional experience, may have powers far exceeding those of our own Board of Control and has direct access to the legislature without the intervention of any layman. In the criminal courts the psychiatrist is more widely consulted and his advice more closely followed than anything dreamt of in this country. Where the court differs from the psychiatrist, the result is almost invariably a more lenient sentence: this is an answer to those who fear that reference to a psychologist means "coddling the criminal." The commitment regulations vary with different States, and in Maryland a patient can be committed for permanent detention on the certificate of two medical practitioners without judicial intervention. The system works well; actions for illegal commitment are no commoner there than elsewhere and practically never successful.

Another direction in which advance has been made in America is in psychiatric education, both of the public and of the profession. In contrast to the scanty instruction of students which is still a reproach to medical education in this country, the American medical schools teach medical psychology and psychopathology in each of the four years of the course; the students examine mental and neurotic cases, and they learn the psychological aspect of the ordinary hospital case. America has often been accused of over-specialisation, but she is not unaware of her own risk, as is shown by the recent foundation of the Institute of Human Relations at Yale. Here the future doctor, lawyer, clergyman, and business man are to come together for a common grounding in

psycho-biology. Dr. MAPOTHER summarises the situation by saying that American psychiatry is characterised by the domination of the medical spirit and the instinct to look rather to the future than at the present. Nevertheless, there is room for doubt whether the methods adopted in the United States of America are necessarily of value here. The conditions vary so greatly; the attitude of the public is so different; and more than this, the available resources are unlike. Conditions exist in America that would not be tolerated here, even though the scientific work in certain directions is far in advance of ours. It would perhaps be unwise to think of any country as being pre-eminent in psychiatry. Dr. MAPOTHER himself is sceptical of the Mental Treatment Bill, and, as we have pointed out, certain of its tendencies appear to be unfortunate. Whether he is justified in speaking of England in this respect as a lawyer-ridden country and in extolling the States as being comparatively free from this alleged evil is a matter of opinion. Some of his illustrations of procedure strike us here as odd. The power to use a habeas corpus procedure, which resulted in a patient shooting the lawyer who was instrumental in gaining him freedom, is a case in point. Some have wondered whether as a matter of fact there is more liberty in America than in our own land. At any rate, judging from what we read, the English are naturally a more law-abiding people; this being so, our machinery for dealing with mental illness may rightly differ from that of America.

The real value of Dr. MAPOTHER's survey, as it seems to us, lies in showing the many and various ways in which America has tackled the problem of mental infirmity. Research, after-care, the study of social and individual conditions, occupation therapy, these are carried to an extent hardly envisaged in this country. Nevertheless the public institutions are very large, often greatly overcrowded, although they have a relatively large and highly trained medical staff. Movement of patients is far more free than here; admissions and discharges are relatively much greater. But when all this has been granted there is somehow left in the mind the query, are the patients better off in America? Have they really a greater chance of recovery? Is their treatment by the State and by the staff of the hospitals more sympathetic than it is in this "lawyer-ridden" country of ours?

A PRESENTATION has been made to Dr. A. Brown Ritchie by members of his staff, on his retirement from the position of school medical officer under Manchester authority.

BRITISH EMPIRE CANCER CAMPAIGN.—At a recent meeting of the Grand Council of this Campaign the following grants were approved: £2500 to St. Bartholomew's Hospital for work including the continuance and development of investigations in the deep X ray treatment of cancer, and the further study of malignant growths by slow-motion photography; £950 to St. Mark's Hospital towards its cancer research work; and £200, making a total grant of £3650, to the Yorkshire Council of the Campaign towards a special statistical inquiry into the incidence of cancer shown by post-mortem investigations at some of the principal Yorkshire, Scottish, and London hospitals. The Council also confirmed a grant of £3000 to the Middlesex Hospital towards its cancer research.

The Council decided to convene an informal meeting to review present activities, and consider what further lines of research might be inaugurated. It will take place shortly after the Midsummer recess.—The Council approved the publication of a popular book on cancer which has been drafted by the investigation committee. This book has been prepared so that it can be appreciated by the lay public.—It was reported that the British Dental Association had nominated Mr. O. H. Hawkins to serve as its representative on the Grand Council, and that, Dr. Powell White having retired through illness, the Christie Hospital, Manchester, had nominated Prof. John Shaw Dunn to serve in his stead.

Annotations.

"No quid nimis."

ROBERT BRIDGES.

THE death on Monday last of Robert Bridges, physician and poet-laureate, at the age of 85, brought to an end an interesting career—especially interesting because the finest flower of his intellectual achievement did not blossom until his last year. An uninformal reading of his life would lead to the idea that he drifted from medicine because he was unfitted for its pursuit, and that when he discovered his metier as poet he was too aloof and too severely artistic to be the interpreter of ideals which would inspire a work-a-day world. Robert Bridges, as a matter of fact, was a successful physician before he allowed the influence of classical studies at Eton and Oxford, and the urge, gradually growing in intensity, of poetic production, to detach him from our ranks. And although much of his poetry was directed to an audience composed of the highly educated, and even of the severely cultivated, neither its melody nor its teaching asked for any extraordinary intellectual grasp from the reader. And the fervour, and patriotism of his singing was slowly making appeal to an increasing number of readers when last year he published the lovely "Testament of Beauty," wherein deep religious feeling was blended with the humanism of medicine and a knowledge of its fundamentals. In Robert Bridges all medicine had a great colleague, and its followers may well regret that his long life is closed.

THE ASTHMATIC REACTION IN CHILDREN.

WORKING in the University Children's Clinic in Berlin, Dr. J. Tüscherer* has analysed the records and made clinical observations on 152 cases of asthma or allied disorders. The diagnosis in four instances proved to be wrong, while in 12 other patients the illness was so short as to make the diagnosis doubtful. Tüscherer prefers the term "asthmatic reaction" for the cases he describes, and he would include under this heading all examples of true asthma, bronchial asthma, and nervous asthma as occurring in adults, the bronchial asthma and asthmatic bronchitis of children, and the spasmodic bronchitis of infants. As regards the mechanism of the attacks he follows modern authorities in analysing this into its nervous and secretory components (spasm plus excess of mucus in the bronchi), but he does not agree that the underlying nervous predisposition to the disease is necessarily inborn. Nevertheless, analysis of the family histories of the patients in this series showed asthma in the father in 12, in the mother in 11, in the grandparents in 15, and in other relatives in 16; 17 of the asthmatic patients had a family history of nervous trouble. The age of onset of symptoms varied in the series, but Tüscherer shows that first attacks may date back to early life. Three of his patients undoubtedly began to show signs of the asthmatic reaction during the first four months, and he gives details of one of these cases admitted with a respiration-rate of 85 per minute and an acute spasmodic bronchitis, rapidly clearing, at the age of only nine weeks. Subsequent history showed that this early attack was the beginning of the asthmatic reaction in this child. The association of asthma in children with the "exudative diathesis" of Czerny is emphasised, and the relation of infantile eczema to asthma is also brought out in this series. The alternation of asthma and eczema in the same patient was well illustrated in some of the cases analysed. The influence of infectious fevers in bringing out a latent disposition to asthma was seen in many instances. In the whole series of 152 cases the first asthmatic symptoms followed whooping-

* Jahrb. f. Kinderh., 1930, cxxvii., 20.

cough in 22 patients, measles in 11, and pneumonia in 22. In connexion with the last-named there is, of course, the fallacy that so-called pneumonia may really have been the first attack of asthma. Nasal catarrh was present in 73 cases, enlarged tonsils in 29, a tendency to run a temperature without obvious cause in 27, and "chills" preceding the asthmatic attack in 31. Climatic influences were also considered, and in 29 patients it was thought that the asthma was influenced by the weather. Psychical shock appeared to be responsible for precipitating the asthmatic attack in one case. As regards pathogenesis, Tuscherer sums up in favour of an unstable respiratory centre where stimuli both from higher parts of the brain and from other parts of the body may precipitate an attack. Prognosis can be summarised by saying that of the 152 patients 35 had lost their asthma before puberty, and 39 became clear of attacks after puberty.

THE HOSPITAL PATIENT FROM HIS OWN POINT OF VIEW.

THE charge is often levelled against hospitals that the patient is regarded as merely a case, while his personality is largely, if not entirely, neglected. To a certain extent this is inevitable, and for the most part those admitted are so appreciative of the medical and nursing attention they receive that they do not greatly resent the lack of that personal interest which forms a large part of the private practitioner's business. They are also marvellously tolerant of long delays and complicated processes which are never explained to them. Nevertheless there has been a definite change of attitude since the hospital service has been extended to the middle classes. Dr. W. S. Goodale¹ who takes up the cudgels on behalf of the patient as an individual, urges the speeding-up and synchronising of such preliminaries as the admission history, the bath, the interview with the almoner, the students' and house officer's history and examination, and the delayed and all-too-brief and uncommunicative visit of the physician or surgeon. The patient's next trouble is his food. The "house diet," says Dr. Goodale, "unalterable as the laws of the Medes and Persians, and garnished with a prune, apparently is planned for its calories and vitamins but with little regard, if any, for individual taste, much less national appeal." Why should not attractive alternatives be offered? He next attacks hospital smells and sounds, and contrasts the filtered, washed and cooled air of the picture palace with the mixed odour of iodoform, carbolic, creosote, sweat, bad teeth, and boiling vegetables that the hospital patient sometimes has to breathe. He also urges daily visiting for all convalescent patients; since this is allowed in private wards it cannot be consideration for the patient's welfare that restricts visiting in the public ward to four or five hours a week. He criticises the inadequate supply of nurses, and remarks, "If there is one nurse allotted to 10 or 12 patients during the day-watch and one nurse to 18 or 20 during the night-watch, the observing patient is soon able to phrase a fairly good working definition of 'delayed service.' Why not a patrol nurse whose sole duty is to visit all patients voluntarily and to inquire whether or not she can be of service?" The tediousness of convalescence can be greatly reduced by a good library service and an educational occupation system. His proposed social service involves several revolutionary suggestions. The remark "no inquiries about patients can be answered by telephone" is familiar enough in the telephone directory and is certainly necessary as long as one harassed porter has to attend two large switch-boards as well as perform the ordinary duties of a door-man. Dr. Goodale suggests that a special social service should deal with all contacts with the

public, providing a medium through which relatives and friends can blow off steam, whether by way of anxious enquiry or complaint. This department would also take over some of the duties now undertaken by the almoner, would see to the notification of relatives when a patient is on the danger-list, and make sure that every patient on discharge had suitable clothing, hair-cut and shave, at least a shilling in money, a proper destination, and an escort. It would also see to the reception of mourners and undertakers if the patient died. The anxiety of relatives is often very seriously increased by their inability to get any interview with a doctor, and Dr. Goodale suggests that representatives of the house staff should be present in the lobby or a special room at certain fixed hours of the day, ready and willing to meet the relatives of their patients. We are hardly yet ready in this country for his final comparison of a hospital with a hotel, and his suggestion that hospital management has much to learn from successful inn-keeping. Hotel employees, he says, have been trained to assume the attitude that the guest is always right and hotel managers have accumulated fortunes by astutely commercialising the Biblical aphorism "A soft answer turneth away wrath." Hospital employees and managers have both these lessons to learn. They are seldom, he admits, positively cruel, but their ignorance of psychology and their lack of attention to the personal aspects of their patient result in a negative cruelty expressed by a lack of that inexhaustible supply of kindness, consideration, and forbearance that the sick guest needs so much more than the healthy.

Dr. A. T. Holbrook, in an article accompanying Dr. Goodale's, maintains that hospitals are used too much for cases which might be treated outside them if the general practitioner made more careful examinations and used comparatively simple laboratory equipment in his own surgery. He also blames the practitioner for the state of affairs of which he complains so bitterly—i.e., that he is becoming a mere directing-post to specialists. The general practitioner of the future, he says, must have two qualifications—competence and honesty. He must be able to recognise and willing to call in help for conditions that are beyond him, but he must also be prepared to do conscientious and scientific diagnostic work in a measure quite un contemplated by his predecessors.

THE PATHOGENY OF ANGINA PECTORIS.

MANY hypotheses have been formulated to account for the pain of angina pectoris, but of them two only have received much support. The one attributes the condition to disease of the aorta, the other to coronary arterio-sclerosis. Neither is completely satisfying, for the accused organ has been found healthy at autopsy in unquestioned cases of angina, while gross lesions of the aorta or of the coronary arteries may be present in patients who have never experienced anginal pain. The absence of pain in patients with advanced coronary disease may possibly be accounted for by a hyposensitive nervous mechanism; but the occurrence of angina in the absence of any obvious anatomical lesion calls for further explanation. Probably it would be more correct to speak of angina, not as a disease, but as a syndrome which may be attributable to various causes which all act in a similar way—namely, by producing anoxæmia of the heart muscle. The whole subject is critically reviewed by Dr. Douglas Hubble elsewhere in our present issue. Diagnosis cannot be regarded as satisfactory until it is possible to say which cause of pain is operative in any particular case. Already one definite pathological entity has been separated off from the group of lesions which may produce cardiac pain. That condition is cardiac infarction following thrombosis or embolic occlusion of one of the larger branches of the coronary arteries. In addition to pain following the anginal distribution cardiac infarction is accompanied by dyspnoea,

¹ Jour. Amer. Med. Assoc., March 29th, p. 905.

vomiting, shock, and other symptoms, which together with the duration of the pain itself render its recognition possible during life. The diagnosis of coronary occlusion once infarction is complete presents but little difficulty, and the problem which now requires solution is how to differentiate the pain associated with the earlier phases of this process from that of ordinary angina. Dr. Hubble in his paper describes a case which has an interesting bearing on this problem. In his patient the actual occurrence of infarction was preceded during a period of several weeks by prodromal anginal attacks of increasing severity. Dr. Hubble emphasises the fact that, in these attacks, the pain, so far as its character and distribution was concerned, differed in no way from that of simple angina. The difference was that the attacks occurred quite apart from exertion or emotion and were not relieved by rest. They were often accompanied by dyspnoea. The pain in this case was temporarily relieved by nitrites, but returned as soon as the effect of the drug had worn off. Dr. Hubble suggests that the action of nitrites in relieving the pain of angina is due partly to a lowering of blood pressure and partly to a coronary dilatation which temporarily improves the collateral circulation; but, as he goes on to point out, a lowering of the general blood pressure may accelerate thrombosis. For this reason alone even during the prodromal phase, nitrites are contraindicated in the treatment of coronary occlusion, and it is important that we should be able to differentiate between these forerunners of myocardial infarction and the ordinary attacks of simple angina.

MEDICAL ADVICE ON BIRTH CONTROL.

A COPY of certain correspondence which has taken place between the Society for the Provision of Birth Control Clinics and the General Medical Council has been sent to us, and although nothing will be served by publishing the whole correspondence, the question raised in it is an interesting one from the ethical side. At the beginning of March a letter was sent by the secretary of the Society to certain practitioners, asking if patients seeking advice on birth control questions could be referred to them; for the Society receives letters begging information from people not in touch with any of their clinics, and realises that answers can only be given adequately by a qualified medical practitioner. The invitation to co-operation was sent by one of its recipients to the General Medical Council, with the result that a communication was received by the Society from the Registrar enclosing the Warning Notice of the Council in regard to advertising and canvassing, and going on to say "if an allegation were received that this (notice) was being contravened together with adequate evidence the matter would receive very careful consideration." The Society has replied to the Council expressing a desire to keep the rules of the Council, but pointing out that the Warning Notice is not relevant, when the Council replied upholding the contrary view, and in so doing could justify its contention. Yet the matter is not quite so simple as either the secretary of the Society for the Provision of Birth Control Clinics on the one hand, or the Registrar of the General Medical Council on the other, appears to consider. From the point of view of the Council it must be pointed out that it is proposed through the instrumentality of the Society to send women to consult doctors other than their own—that is to say, that the practice of one doctor through the instrumentality of the Society may be extended at the expense of that of another doctor. But from the Society's aspect of the case, it may be pointed out that before the instrumentality of the Society is sought, the patient has, in most or all cases, already decided to obtain certain medical advice elsewhere than from her doctor—in other words, she is intending to exercise that free choice of doctor which is associated with all modern relations between the public and the medical profession.

Advice on the subject from the medical aspect cannot be given by correspondence, while a patient might desire particular counsel from someone other than her own family practitioner. The Society should certainly point out to the medical practitioners who express themselves willing to help them the necessity, first, of keeping the patient's own doctor informed of the advice given, and, secondly, of impressing upon the patient the fact that this advice is being given in a special manner, and not in the routine of practice.

THE CURRICULUM IN RUSSIA.

ACCORDING to the *Moskauer Rundschau* of April 13th a Russian national conference was recently held, at which proposals for the reform of medical education were discussed. A plan for the reorganisation of medical schools, as proposed by the authorities, was considered and the conference suggested the lines on which the chief features of the plan should be embodied in practice. It is proposed to have three different kinds of medical faculty at the universities, instead of one uniform type as hitherto. The three types of faculty will be: (1) general medicine; (2) public health and preventive medicine; and (3) maternity and child welfare. The faculty of general medicine will include several subdivisions, such as general treatment, surgery and internal medicine, and will also have a maternity and child welfare branch. The public health faculty will provide courses of studies intended to produce experts in general sanitary science and its branches, such as epidemiologists, experts in the hygiene of housing, and specialists in industrial disease. The third type of faculty will educate specialists in maternity and child welfare, and in children's diseases. The length of a medical course in any one of the faculties will be three and a half to four years. Some of the medical students will be evening students, and at the largest medical schools complete evening medical faculties are to be opened. It is stated that this will enable the number of medical students to be increased to 11,000 even in the current year; there were 3300 last year. The conference recommended that the use of Latin medical terms, "handed down from the Middle Ages," is objectionable. Appropriate Russian words are to be substituted for Latin terms in the study of medicine, in all medical clinics and in prescriptions.

THE ANTI-INFECTIVE POWER OF CAROTENE.

Prof. Edvard Mellanby and Mrs. May Mellanby have a claim for subjects in experimental dietetics which hold great possibility of benefiting the public health. Apart from their well-known work on rickets and on dental caries, Prof. Mellanby has recently concerned himself with the study of vitamin A as an anti-infective agent, and offers observations which may prove of much importance in preventive medicine. It has long been known that in rats whose diet is deficient in vitamin A the mucous membranes throughout the body become especially liable to septic infection. This is seen more particularly in the eye, the respiratory passages and adjoining glands, and the bladder, and in drawing attention to the phenomenon Prof. Mellanby has pointed out that the septic foci of inflammation which occur in the rat are also found in man.¹ Within the last two years the whole question of the relation of carotene to vitamin A has come once more under consideration, and there is now no conflict of opinion that purified carotene can act as an adequate source of vitamin A, although the nodal problem remains unsolved, whether carotene itself functions as vitamin A, or whether it contains an impurity which defies all ordinary means of separation. In their most recent contribution, Green and Mellanby² do not set themselves to attack this problem, but seek to ascertain whether, in vitamin A deficiency, carotene can supply

¹ Green, H. N., and Mellanby, E.: Brit. Med. Jour., 1928 II., 691.

² Green, H. N., and Mellanby, E.: Brit. Jour. Exp. Path., 1930, XI., 81.

the anti-infective agency as well as classical, colourless vitamin A was found to supply it. To those who have worked with purified carotene its complete equivalence with colourless vitamin A from animal sources is already an accepted fact, but there are several other points in this paper which require notice. It is made clear, for instance, that carotene may be of value in any case where vitamin A therapy is desirable, for it lends itself to accurate dosage, and can be administered without the accompaniment of the various lipid liver derivatives which usually form part of vitamin A concentrates of animal origin. Green and Mellanby have further made a significant observation on dosage. They find that while 0.005 mg. of carotene will promote growth resumption in the rat, a much larger dose—something like 0.02 mg.—is needed for complete protection of the animal from mucous membrane infections. It thus appears that the outward signs of vitamin A deficiency may be suppressed at a certain dosage, and the deficiency may be manifest solely by the liability of the mucous membrane to infection. This observation has an obvious and probably very important bearing on the relation of vitamin A deficiency to mucous tract infection in human beings. The nature of the disposition to infection which the deficiency causes is not further illuminated, but it is hoped that the experimental use of carotene may throw light on it.

Carotene, or related lipochrome pigments, is widely distributed in the world of living organisms,³ but is derived in especially large quantity, as its name implies, from the carrot. If the animal experiments are found to apply to human beings they will go far to justify the enthusiasm which vegetarians often profess for these vegetables.

In the North, it may be noted, an old recipe for treating a sick horse is, "Give him a feed of carrots and leave the light on."

AN EXPERIMENT WITH BCG.

THE remote country district of Trysil in Norway has been chosen for an interesting mass experiment. Since August, 1927, it has been visited by five successive expeditions of doctors and medical students who, up to August, 1929, had carried out Pirquet tests in 2427 healthy persons, 1079 of whom were Pirquet-negative, and were inoculated with BCG tuberculosis vaccine once or oftener. In an account of this work by Dr. O. Scheel, Dr. R. Schultz-Haardt, and Dr. T. Skaar in *Norsk Magazin for Laegevidenskaben* for March, a résumé is given of their findings. The technique of the inoculations with BCG was not uniform; in 1927 and in August, 1928, it was injected into the subcutaneous tissues in doses of 0.05 or 0.025 mg. This technique rarely gave rise to abscesses. In November, 1928, the BCG was deposited in the deepest part of the cutis, the point of the needle passing from the subcutaneous tissues upwards to the deeper structures of the skin. The dose was 0.025 mg. and the incidence of abscesses was high (38 per cent.). In August, 1929, the dosage was reduced to 0.02 mg. and the vaccine was deposited just under, or in the deepest layers of, the cutis. Infiltration of the skin at the site of inoculation occurred sometimes directly or a few days after it, but more frequently from six weeks to three months after it. These infiltrations, up to the size of a pea, lasted for weeks and even months, but within a year they had either disappeared completely or had left a small scar or a bluish discoloration. They often ended in abscess formation, the pus being evacuated from one to three months after the inoculation. Spontaneous evacuation could be avoided by aspiration, repeated if necessary. The more superficial the level at which the BCG was deposited in the tissues, the greater was the proportion of the positive Pirquet reactions after the inoculation. Thus, when the BCG was administered by subcutaneous injection, the Pirquet test

became positive only in 31 per cent., whereas it did so in 81 per cent. of the persons given the vaccine by cutaneous inoculation. The same was true of the two other sequels of the BCG inoculation—infiltration and abscess formation—which became more frequent as the level at which the vaccine was deposited approached the surface of the body. It is not yet clear whether these three sequels to BCG inoculation can be correlated with a comparatively high degree of immunity; the subsequent fate of the persons in Trysil given subcutaneous injections may throw light on this problem when compared with the fate of those given cutaneous injections of BCG. What is already of great practical interest is the tuberculosis morbidity in Trysil since this mass experiment was started. Between the beginning of the experiment and November, 1929, signs of tuberculosis appeared in 20 persons. In four of these cases there was a history of tuberculosis dating back some time—a history obtained in 254 cases. Among 923 persons who had not previously shown any sign of tuberculosis clinically, but who had been Pirquet-positive, there were 10 who developed signs of tuberculosis. Among 171 persons not inoculated, although they were Pirquet-negative when first examined, there were three who subsequently developed signs of tuberculosis. Among the 1094 who were not inoculated, who had previously shown no clinical sign of tuberculosis, and who had given either a positive or a negative Pirquet reaction, there were as many as 13, or 1.19 per cent., who subsequently developed signs of tuberculosis, whereas among the 1079 Pirquet-negative persons who were inoculated, there were only three, or 0.28 per cent., who subsequently developed signs of tuberculosis. In all these three cases the contact which had been the source of infection was discovered, and as in one of these cases the manifestation of tuberculosis (an outbreak of erythema nodosum) appeared only 30 days after the inoculation—i.e., too early for the inoculation to have taken effect—the number of cases in which the inoculation apparently failed to induce immunity to tuberculosis may be reduced from three to two, or from 0.28 to 0.18 per cent. Comparing the tuberculosis morbidity of 0.28 (or 0.18) per cent. among the inoculated Pirquet-negative persons with the tuberculosis morbidity of 1.19 per cent. among the controls who were not vaccinated, the authors of this report claim that they have already made out a very convincing case for BCG inoculation of Pirquet-negative persons at various ages; but they admit that their figures are still too small, and the observation period too short for a statistical analysis which will conform to all the conventional requirements of a study of this kind.

MOSQUITO PROOFING IN BARRACKS.

MOSQUITO proofing in barracks has done much to prevent malarial infection in the army in India for seven years; we learn from a recent paper by Dr. R. Reitler¹ that it is also being used in industrial buildings, for he safeguarded the workers at a power station of the Palestine Electric Corporation on the upper waters of the Jordan in this manner in 1927. He admits that the destruction of the larvæ is the most complete of antimalarial measures, but observes that the expense may be prohibitive, though to keep mosquitoes away from the men by screening may be practicable. In the case of the Jordan water nine months remained, as it happened, before the Jewish workers could be employed at the spot, so there was time to build satisfactory houses for them, the men building them being, meanwhile, protected with nets, constantly supervised. The 40 houses were cottages of cement-concrete, with overhanging roofs, the windows and ventilators were protected with wire gauze, and the entrances with double-doored porches.

³ See THE LANCET, 1929, II., 392.

¹ Arch. für Schiffs- und Tropen-Hygiene, vol. xxxiv., Part 4 (April, 1930), p. 198.

The houses proved inadequate in size or number, and the overflow workers were lodged in ordinary huts with well-supervised mosquito nets, thus providing a control for comparison with the special houses. A man went round daily to catch and destroy all mosquitoes, and found in the first seven months 12 in the houses, 1902 in the huts, 3017 in open clothes lockers; so the screening of the houses was effective. In 11 months 17 fresh infections occurred among 77 men in the huts (2.0 per month per cent.), but only 16 among 377 men in the houses (0.38 per month per cent.). Thus the benefit from careful proofing is evident. In one month the gauze of one house was damaged, and 100 mosquitoes were found in that house in one week, and a case of malarial fever developed there within three weeks. Dr. Reitter quotes with approval from J. B. Hlana² that in the tropics mosquito proofing is as necessary to a house as is in the Arctic a source of heat. By itself, he says, proofing does nothing to reduce malaria in the area, unless as here the mosquitoes are captured and destroyed and the larvæ pursued in the usual ways.

THE BRITISH ASSOCIATION AT BRISTOL.

THE ninety-ninth annual meeting of the British Association will be held at Bristol early in September next, under the presidency of Prof. F. O. Bower, F.R.S. The Association has met at Bristol on three previous occasions, the first in 1836 when Lord Northampton, its President, laid the first stone of the Clifton Suspension Bridge, and the Geological Section had first-rate opportunity for field survey in the cuttings then being made for the Great Western Railway. At the meeting in 1875 Sir John Hawkshaw presided, and 1898 was memorable for an address by Sir William Crookes on the future wheat supply. Since that date Bristol has become a University city and the Association will meet this time in some of the finest academic buildings in the world, thanks to the generosity of the Wills family and the designs of Sir George Oatley. The programme will open on the evening of Wednesday, Sept. 3rd, with the presidential address in the Colston Hall on Size and Form in Plants. Addresses by sectional presidents to be delivered during the ensuing week will include (Chemistry) Prof. G. T. Morgan, F.R.S., on a State Experiment in Chemical Research; (Anthropology) Dr. H. S. Harrison on Evolution in Material Culture; (Physiology) Prof. H. S. Raper F.R.S., on the Synthetic Activities of the Cell, and (Psychology) Prof. C. W. Valentine on the Foundation of Child Psychology. Many of the discussions will be of wider scope through the merging of two or more sections for the purpose. For instance the sections of botany and agriculture will discuss the Mineral Element in Plant Nutrition; the Sections of physiology and psychology will discuss In What Sense Can We Speak of Primary Colours? And the three sections of geology, geography, and anthropology will discuss the Relation between Past Pluvial and Glacial Periods. These discussions will afford the opportunity on which the Association is based for conference and cooperation between scientific workers and others interested in all departments of science. Evening discourses will be given on Sept. 5th by Prof. E. V. Appleton, F.R.S., on Wireless Echoes; and on Sept. 9th by Dr. R. E. Slade on the Nitrogen Industry and our Food-supply. Public lectures will be arranged in Bristol and the neighbouring towns. The acting general secretary of the Association for 1929-30 is Prof. F. J. M. Stratton, and the local honorary secretaries for the Bristol meeting are Dr. W. Ludford Freeman, Dr. Bertram H. Rogers, and Prof. A. M. Tyndall. Between now and the Bristol meeting a loan exhibition of antiquities from Southern Rhodesia will be on view in London at the Assyrian basement of the British Museum. These are the result of excavations undertaken for the Association by Miss G. Caton-Thompson at Zimbabwe and other Rhodesian sites last year. Admission will

be free during the hours when the museum is open. Future arrangements include a centenary celebration in London in September of next year, and meetings at York in 1932 and Leicester in 1933.

CYANIDE POISONING IN HOTELS.

Dr. Huntington Williams¹ records a number of cases of acute non-fatal cyanide poisoning apparently due to consuming silver polish. In June, 1928, he says, about 30 persons became acutely ill after dinner at a hotel in Utica. No evidence of food deterioration could be discovered, but on examination the powder used for cleaning silverware was found to contain over 20 per cent. of sodium cyanide. It was ascertained that similar cases had occurred at many hotels where this compound and others containing cyanide were used as a routine. Usually the utensils were dipped about once a week in a solution containing the poison, and the result was that ineffective rinsing might easily lead to poisoning of the next guest who used them. Oddly enough, none of the servants employed in cleaning silver seem to have developed symptoms. These were acute gastro-enteritis with vomiting, purging, and later, signs of shock. In one of the cases recorded, diarrhoea was so violent and persistent that finally the patient was passing watery mucus; in another, blood-stained stools were passed. The shock was so severe that in more than one case the illness was critical, with pallor, sweating, dyspnoea, and thready pulse; in several cases also there was albuminuria. The managers of the hotels usually received the explanation with gratitude, and stopped the use of the dangerous preparations. Certain hotels which had received complaints of food poisoning from their guests have been able to record the disappearance of such complaints since these polishes have been abandoned. Legislation to prevent this danger has been attempted in the State of New York, where the sanitary code has been amended to forbid the use of any cyanide preparation or other poison for cleaning nickel, copper, or silverware, or other articles used in the preparation of food. The Department of Health of Newark, New Jersey, has placed a similar ban on the use of poisonous compounds for cleaning silverware, and warnings have been given through the American medical press.

THE DECLINE IN VENEREAL DISEASE.

THE gradual but steady decline of syphilis in European countries since the late war must be attributed largely to the intensive Government campaigns against the disease. The legislative measures employed by various countries provide interesting contrasts.² In Germany every person infected with venereal disease must, by law, attend a doctor, and if necessary his attendance can be enforced until treatment is complete. Though marriage while in an infective state is not at present forbidden, the patient is legally responsible for informing his betrothed of his condition before the marriage takes place. The power to refuse medical care is suspended in the case of venereal disease, and the sale of unofficial remedies is forbidden. This legislation only came into force in February, 1927; but previous public health work had reduced the incidence of syphilis considerably; in 1919 the incidence of new infections was reported as 8.7 per 1000 inhabitants, and in 1927 this number had fallen to 5.8. In the United States of America notification of his disease by the patient is compulsory, but variably enforced in different States, so that statistics cannot be exact. The annual incidence of new cases is estimated at about 1.5 per 1000 inhabitants, while the number of cases treated, old and new together, is roughly 4.2 per 1000. Among the negro population the incidence is higher,

¹ Jour. Amer. Med. Assoc., March 1st, p. 627.

² Bull. de l'Office Internat. d'Hyg. Publique.

standing at 2.4 per 1000, while the percentage of positive Wassermann reactions stands at 20 to 24. A steady decrease in syphilis in the army coincides with an equally steady, unexplained, rise among marines. The death-rate from general paralysis has fallen, but whether this is due to more efficient early treatment, reduced incidence of syphilis, or the use of malarial therapy cannot yet be decided. Probably all three have played a part. In France the incidence of primary infections is said to have fallen from 21.1 per 1000 in 1917 to 2 per 1000 in 1928; stillbirths fell from 48.3 per 1000 births (of living and dead children) in 1916 to 37.6 per 1000 in 1928. The venereal service has been developed, and propaganda has been undertaken on a large scale. In Algiers an energetic attempt is being made to combat these diseases, but it is still too early to demonstrate marked results, though the number of skin lesions among the populace seems to be decreasing rapidly. In Great Britain the effects of propaganda are shown by an increasing tendency for patients to continue treatment until cure is complete. Seventy-seven laboratories in England and Wales undertake the performance of the Wassermann reaction. The incidence of new cases is now assessed at less than one-fifth of the average annual incidence between the years 1911 and 1918. Infant mortality from syphilis has fallen from 2.03 per 1000 births among children under one year in 1917, to 0.71 in 1928. In Egypt and Turkey anti-venereal campaigns are being undertaken, but here again it is too early to estimate their results. In Yugoslavia stringent legal measures are taken against persons who infect others with disease during the course of their own treatment.

TRANSMISSION OF THE VIRUS OF DENGUE.

THOUGH a number of different mosquitoes have been incriminated as possible dengue vectors, the only species accepted as the unquestionable carrier is *Aedes aegypti* (*Stegomyia fasciata*). Certain observers have suggested the possibility that other species, including *A. albopictus* (*S. scutellaris*, Walker), may also transmit the disease, but the results obtained by Koizumi, Yamaguchi, and Tonomura when they investigated the rôle of this insect were inconclusive. It appears that in the Philippine Islands *albopictus* is widely distributed; the larvae are often found in the same breeding places as *aegypti*, and the relative proportion of *albopictus* has been shown to increase in June and July at which time dengue fever was prevalent in Manila. Simmons, St. John, and Reynolds' report experiments with a strain of dengue fever maintained since December 1928, by passage through six different batches of *aegypti* and six human volunteers. The imagines of *albopictus* had emerged from larvae collected about Manila. On July 16th, 1929, 100 female mosquitoes of this species were given an opportunity to feed on a volunteer patient who had developed typical symptoms of dengue fever 12 hours earlier. The successfully fed mosquitoes were kept for a minimum period of 13 days before tests were made to determine their ability to transmit dengue to man. Each volunteer was isolated in a screened cubicle in a screened ward. The supply of virus was obtained in the first instance by transference from one volunteer to another through selected *aegypti*. Finally one volunteer developed dengue from the bite of a single mosquito and upon his blood a group of 54 female *albopictus* were fed. After periods of 15 and 20 days respectively, small groups of this batch of mosquitoes were tested on two volunteers, both of whom developed dengue fever five to seven days later. In all, seven successful transmission experiments were carried out, indicating that *albopictus* is highly susceptible to infection with the dengue virus. From the evidence already collected regarding the widespread distribution of *albopictus* in the Far East,

it is obvious that this mosquito must be considered as a serious factor in the dissemination of dengue fever.

Not only has it been found possible to pass the dengue virus from volunteer to volunteer with precision, but also to transfer the virus from infected to normal *aegypti* without passage through a vertebrate host.² This was done in an ingenious manner by filling a cell (an ordinary rectangular staining dish) with citrated human blood and macerated dengue-infected *aegypti* over which the fresh depilated skin of a guinea-pig had been stretched and clamped. The apparatus was kept at 37°C. and inserted into a cage containing normal laboratory bred insects. The mosquitoes were at once attracted to the skin and in a short time most of them became engorged with the blood mixture. Subsequently they produced typical dengue fever in two American volunteers after an incubation period of six days. This method of infecting mosquitoes in the laboratory promises to be of distinct value in the study of virus diseases transmitted by mosquitoes.

THE CASSEL HOSPITAL.

THE current report of the Cassel Hospital for Functional Nervous Disorders at Peshurst deals with the patients who were under care in the calendar year 1928. Of 67 cases of anxiety state, 60 improved while in hospital, and 54 were known to be well and improved a year later. Of 25 cases of hysteria, 19 improved while in hospital, and 15 of them were known to be well and improved a year later. Two obsessional compulsive cases both obtained lasting benefit. The 16 psychoneurotic patients who did not improve or who relapsed within the year are reviewed in detail. Three who improved but relapsed were all people of poor morale, and their temporary improvement could only be attributed to their residence in a sheltered environment. None of the patients discharged during 1928 subsequently claimed to have been cured elsewhere. According to custom the group labelled "psychopathic personalities" was kept as small as possible; four out of the nine patients comprising it showed marked improvement, and the others suffered from alcoholic or drug addiction. Of the 17 patients with schizophrenic symptoms two recovered, and out of nine depressed psychotics two went out well, but one has since relapsed, and three of those who were discharged unimproved have since recovered. Two patients suffering from hypochondria were discharged unaltered. Full tables are given in the report, and the individual cases described will be of interest to all who have to deal with problems of this kind.

THE Rockefeller Foundation has made a grant of £2000 a year for two years towards the work of the National Institute of Industrial Psychology. The institute, it is stated, has already received £14,500 from the Foundation.

THE library of the Royal Society of Medicine is in future to remain open until 10 P.M. on Thursdays as well as on Tuesdays and Fridays. All Fellows not resident or practising within one mile of the Society's house may now have books sent to them from the library, carriage paid.

Sir Alfred Watson, the Government actuary, has issued a report on claims for benefit under the Insurance Acts received by a representative group of approved societies. It is shown that the proportion of men claiming sickness benefit rose from 14 per 100 in 1921 to 23 per 100 in 1927, corresponding increases being recorded among women. In the latter year 430 out of every 1000 women drew sickness or disablement benefit, or both. Sir Alfred believes that the conditions of 1927 have not subsequently been alleviated.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

LXIX.

SIGNIFICANCE OF PROTOZOA, SPIROCHÆTES, AND HELMINTHS IN THE BLOOD.

PART II.*

Trypanosomes.

AFRICAN trypanosomiasis is the most typical tropical disease in so far that it can be acquired only in tropical Africa. The classical picture of the fully developed trypanosomiasis is seldom seen in European patients. The cardinal signs of trypanosome fever, its adenitis, the typical rash, and the nervous involvement may not all be evident at the same time, and yet the patient may be suffering from trypanosome infection. In the early stage of the infection the parasite circulates in the blood stream, but later it invades the central nervous system, penetrating the brain substance and invading the cerebro-spinal fluid. Even in heavy hæmic infections in man the trypanosomes are never so abundant in the blood stream as they are in artificially infected animals, such as the rat and the guinea-pig. Moreover, experience tends to show that the abundance of these parasites in the peripheral blood does not necessarily indicate that the disease is more severe or less easily curable than when they are scanty and extremely difficult to demonstrate. Two forms of human trypanosomes are recognised in Africa, an acute form due to *T. rhodesiense* and a more chronic and less virulent form due to *T. gambiense*. It is difficult, almost impossible, to differentiate these two diseases by the morphology of the circulating trypanosomes, and their identity can be determined only by sub-inoculation into susceptible laboratory animals. On the whole it may be said that in *rhodesiense* infections the trypanosomes are more abundant in the blood stream and that they tend to recur in showers, each corresponding to an increased pyrexia and an intensification of the objective symptoms of the disease. In the microscopical diagnosis of a suspected case prolonged and careful search of the blood is necessary. A wide field of the blood film must be examined; it is inadvisable to search with high powers of the microscope, for the trypanosomes can be readily picked up with the 1/8 in. lens and a wider field of blood thereby surveyed. The clinician cannot, however, rest assured with one negative blood examination for trypanosomes. I have had cases in which the organism has only been demonstrated after the twentieth consecutive test. As has already been stated, the parasite tends to appear in waves. The most likely period for successful search is when the patient exhibits by malaise, headache, splenomegaly, adenitis, or the characteristic rash, an exacerbation of symptoms. The recognition of one undoubted trypanosome in the blood film is an absolute assurance of a correct diagnosis. I have had two cases in Europeans, both terminating fatally, in whom only one trypanosome had been found in the blood stream during observations extending over one year, and in both there was a heavy infection of the brain and cerebro-spinal fluid with the organisms. In a wet blood examination auto-agglutination of the erythrocytes, which is frequently seen in trypanosomiasis, is very suggestive, though not necessarily pathognomonic. The employment of thick blood films is of doubtful advantage; centrifugalised citrated blood taken from a vein may be used. Puncture of the affected lymphatic glands and examination of the

abstracted lymph for trypanosomes may give a greater chance of a positive diagnosis than blood examination. In cerebral trypanosomiasis the trypanosome may or may not be present in the cerebro-spinal fluid but the cell or globulin content is invariably increased so that, in the absence of any other positive evidence, this should be considered conclusive. Inoculation of 2 to 10 c.cm. of suspected blood into some susceptible laboratory animal may be tried, though with the non-virulent strains of *T. gambiense* even this may not be effective in proving the diagnosis.

There is another form of human trypanosomiasis, Chagas' disease of South America, caused by *Trypanosoma (Schizotrypanum) cruzi*. It is primarily a disease of the armadillo and occurs as an accidental infection mostly in children, in whom the parasites may be found sparingly in the blood.

Leishman-Donovan Bodies.

Kala-azar is a tropical fever, with splenomegaly, great emaciation, and enlargement of the liver which has to be differentiated from chronic malaria, with which it has many features in common. The Leishman-Donovan body, the specific parasite, cannot generally be demonstrated in blood films, so that other criteria, such as the associated fever, the splenomegaly, the characteristic leucopenia, and a positive serum-formalin reaction must be taken. The diagnosis is clinched by splenic or hepatic puncture and the demonstration of the parasite in films of pulp withdrawn from these organs. At the same time the abstraction of 2 c.cm. of blood from a vein into 1 c.cm. of sodium citrate solution in a sterile test-tube is recommended. The deposit at the bottom of the tube is inoculated into tubes of Novy, Nicolle, and MacNeal's medium and incubated in a cool incubator. By this means it is possible in a large percentage of cases to culture the organism from the blood. In some forms of kala-azar, notably in Madras and Assam, the parasite can be found in the blood in about 20 per cent. of cases examined, especially if thick blood films are used and when the blood is diluted in Locke's solution and subsequently centrifuged. If all the available methods are employed, the diagnosis of kala-azar is rarely missed.

The Treponema of Relapsing Fever.

Relapsing fever is a widespread and almost cosmopolitan disease of very variable intensity. The most virulent is the "tick fever" of Central Africa. The *treponemata*, or spirochætes, are usually demonstrable in the blood in the febrile periods, often in great numbers, and they are easily detected in blood films stained by Leishman's stain. But there are mild cases in every epidemic in which the parasites are very scanty in the peripheral blood and then thick blood films have to be employed for their demonstration. For the proper appreciation of the diagnosis of relapsing fever it is necessary to remember that the parasites are completely absent from the peripheral blood during the apyrexial period and that in the febrile paroxysms, even when the patient is acutely ill with symptoms of the disease, the spirochætes become broken up and disappear 48 hours or so before the crisis. It may therefore be necessary to make a diagnosis of relapsing fever in the absence of a positive blood examination. In this disease there is a well-marked polymorphonuclear leucocytosis which persists during pyrexia, but disappears during apyrexia. A leucocytosis may therefore be of considerable assistance in suggesting the diagnosis.

Leptospira Icterohæmorrhagica.

The organism responsible for infective jaundice, or Weil's disease, the *Leptospira icterohæmorrhagica*, exists in the blood stream in the febrile period, and may be transmitted to guinea-pigs by intraperitoneal injection of whole blood. Indirect methods of diagnosis have to be used, since this organism can hardly ever be detected by ordinary blood film examination.

* Part I. appeared last week.

The Filaria.

It is generally assumed by those who have not practised in the tropics that *Filariasis* is merely of academic interest, but this is by no means true. The most important parasite is *Filaria bancrofti*, in which the adult worms inhabit the lymphatic channels, while the corresponding embryos, or *microfilariae*, are found circulating in the blood stream. This filaria gives rise to a number of clinical manifestations, of which filarial adenitis, hydrocele, filarial lymphangitis, and elephantiasis are the chief expressions. The most ready method of making a diagnosis is by the discovery of the microfilariae in the blood stream, and, as is well known, in the typical *F. bancrofti* infection, these minute nematodes appear in the peripheral blood only during the hours of night so that in a straightforward case of filariasis only night specimens of blood will be positive. It is necessary to take enough blood to render discovery of microfilariae possible. Thick films only should be used. In the Pacific variety of *F. bancrofti* the embryos appear in the peripheral blood by day as well as by night, a circumstance which cannot as yet be satisfactorily explained. Many factors combine to render diagnosis of filariasis by blood examination extremely difficult. It has been found that the adult parasites can exist for several years in the body without the presence of microfilariae in the blood stream and also that the more damage the adult worms produce in the tissues, the more difficult it is for the corresponding microfilariae to enter the blood. So that we are presented with this curious anomaly—namely, that the more extensive the external signs of filariasis become, the less easy is it to make a positive diagnosis by blood examination. Under these circumstances other aids to diagnosis must be called into operation. *Filaria bancrofti* infection gives rise to a considerable degree of eosinophilia, usually ranging from 15–20 per cent.

In *Filaria loa* (*Loa loa*) infections, which prevail on the West Coast of Africa, a somewhat similar problem presents itself. The patient may suffer from manifestations of this infection and be conscious of harbouring filaria worms in his body for as long as six years without at the same time exhibiting the characteristic microfilariae in the blood stream. These embryos appear in enormous numbers in the daytime only, in contra-distinction to the habits of *F. bancrofti*. *Loa loa* gives rise in the stages of invasion to a very high eosinophilia, possibly up to 60 per cent., and this eosinophilia may be an important diagnostic pointer when microfilariae cannot be found.

Filaria perstans (*Acanthocheilonema perstans*) is another parasite prevalent in Central Africa. The patient may harbour several adult nematodes for years without the appearance of the characteristic unsheathed microfilariae in the blood. This worm also produces a high degree of eosinophilia, which may constitute the only tangible evidence of the presence of the parasite in the body. The microfilaria *perstans* can be found in the blood both by day and by night, but it exists usually in small numbers, so that a considerable quantity of blood (20 c.mm. or more) has to be abstracted and searched.

PHILIP MANSON-BAHR, D.S.O., M.D., F.R.C.P.,
Physician to the Hospital for Tropical Diseases, London;
Consultant to the Colonial Office and Crown
Agents for the Colonies.

LONDON LOCK HOSPITAL.—At the annual meeting recently Lord Kinnaird stated that since the inquiry in 1928 every effort had been made to increase the efficiency of the hospital. The board of management has been enlarged to 18 members, one-third of whom, for the first time in the history of the institution, are women. Maternity work more than doubled during the year, and the nursing arrangements of the male hospital have been entirely remodelled. The hospital, which is heavily in debt, has to face the cost of removing the training home to the country.

THE
SURGICAL CLINICS OF HEIDELBERG
AND FRANKFURT-ON-MAIN.

Notes on a Recent Visit by

H. S. SOUTTAR, C.B.E., F.R.C.S. ENG.,
SURGEON TO THE LONDON HOSPITAL.

A VISIT to a foreign clinic is always of interest, for we may be brought into contact with standpoints quite different from our own, and with organisation, methods, and resources from which there is much to be learnt. At the present moment, when relations with Germany are again being resumed, a visit by a group of surgeons to the clinics at one of the oldest universities and at one of the most important business centres is a matter of general interest, and I venture to record our impressions in the hope that others may share our very happy experience.

The Pilgrim Surgeons are a small group who have made it a custom to travel together for a week in every year, to see the work of others, and most of all to see it together. We have visited France, Switzerland, and Holland, and this year left London on Feb. 28th to visit Germany for the first time since the war.

We selected Heidelberg and Frankfurt as being within easy reach and as possessing surgical clinics of renown. Arriving at Heidelberg on Saturday evening we spent Sunday in the enjoyment of its beautiful surroundings. This is essentially a university town situated on the swift stream of the Neckar and surrounded by the wooded hills of the Black Forest. In term time its streets are crowded by its 3000 students, but now it was vacation and there was not one to be seen, but instead there were crowds of children parading the streets in fancy dress, for we had arrived in the middle of the Carnival.

Heidelberg: Prof. Enderlen's Clinic.

Monday morning at 9 o'clock found us in Prof. Enderlen's Clinic. He had very kindly arranged a series of operations for us and on this morning they included a large goitre in a woman of 44, cases of gall-stones in two women of 22 and 31, a gastrectomy for an old perforated ulcer of the stomach in a man of 32, and a perineal excision of rectum in a diabetic man of 47.

Prof. Eugen Enderlen is 67 years old, but there was no sign of his age in his dexterous technique. Although he spent infinite trouble in securing perfect haemostasis, he succeeded in completing this considerable list of operations in three and a half hours, with intervals in which he discussed with us special points in technique. As in all Continental clinics, he has behind him a perfect organisation which includes 10 highly skilled surgical assistants, some of them of professorial rank. At one time we counted in the theatre two sisters, three nurses, and 15 other assistants of various grades, including of course the theatre men, and indeed we were compelled to admiration for an organisation which could make use of so many individuals to one purpose.

On Tuesday morning he performed for our benefit a similar list of operations, cases of goitre, of gall-stones, and of carcinoma of the stomach, and a thoracoplasty for pulmonary tuberculosis. The operations were, moreover, preceded by a tour round the wards commencing at 8 o'clock, and were followed by a demonstration of many old cases of interest. The Professor was tireless, and we began indeed to wonder whether there had not been some mistake in the date of his birth certificate.

The Surgical Unit over which he presides contains 250 beds, including 35 private rooms where patients pay from 8s. 6d. to 13s. 6d. per day. It includes a large out-patient department, and in accordance with continental practice the whole is under the absolute control of the Professor, whose assistants carry out all the pathological investigations he requires, make all the X ray examinations, and carry out much other work which would in England be specialised. The system has undoubted advantages in organisation, but it gives little opportunity to the younger men, whose initiative is unlikely to survive 10 or 15 years in a subordinate position. The wards were plainly but efficiently furnished, and it was evident that the Professor and his staff were on the best of terms with their patients, but we were scarcely prepared for the scene which greeted us in the Children's Ward. The whole of the children were celebrating Carnival. They had all been provided with masks and tin trumpets and our appearance was the signal for a deafening outburst. One small group were doing the thing thoroughly and fixing up one of their number with the aid of yards of strapping on a gallows splint as a case of fracture of the femur.

Of technical details the one which impressed us most was the method almost universally adopted in the treatment of fractures by means of Kirschner's wire. Instead of a thick pin, fine steel wire 1.5 mm. thick is passed through the bone by means of a special form of drill. The wire is then stretched on a frame and to this frame any necessary extension may be applied. The advantage over the ordinary caliper and pins is that the hole of entry is so small that infection is almost impossible, whilst the method may be applied with facility to such small bones as the metacarpals and phalanges. The control thus obtained of the fragments is very remarkable and enables the most perfect apposition to be achieved and maintained.

In the evening the Professor and three of his Assistants joined us at dinner and we spent some delightful hours in discussing the many interests we had in common. One thing struck us very forcibly, the high position held by a Professor in the regard of the public. It is true that Prof. Enderlen's long service has rightly earned for him a great position in Heidelberg, but Germany pays a tribute to intellectual power which is sadly lacking in England. In what English hotel would the social standing of its visitors be advanced quite obviously by the fact that the Professor of Surgery had done them the honour of accepting an invitation to dinner? We have other things to learn from Germany besides technique.

Frankfurt: Prof. Schmieden's Clinic.

From Heidelberg we went on to Frankfurt, and Wednesday morning found us in Prof. Victor Schmieden's Clinic. He operated for us in the magnificent demonstration theatre capable of seating 200 students, and equipped with every appliance that could be desired. He had selected for us two cases; both of considerable interest. The first was one of pyonephrosis of an abnormal kidney situated in the floor of the pelvis. It was approached by a transverse incision above the pubes which divided both recti muscles, and having been fully demonstrated across the peritoneum, it was finally reached from behind the peritoneum of the right iliac fossa and removed. The operation was technically difficult from the great number of blood-vessels which supplied the kidney and which appeared to come from the iliac vessels of both sides, but it was finally completed in a most satisfactory manner. The second operation was for a double duodenal ulcer, and was of interest from the fact that the precise character of the two ulcers and the mobility of the duodenum were all demonstrated beforehand by the radiologist. In accordance with Continental custom, the duodenum was resected and a modification of Polya's operation carried out. It is interesting to notice the disavowal into which gastro-enterostomy has fallen all over the

Continent; and one wonders whether the large incidence of jejunal ulcer which is said to have occurred may be due to some difference in race or in diet, for English statistics show an entirely different picture.

The operations were followed by a lecture by Prof. Hans Holfelder on deep X ray therapy. He expressed the opinion that wave-length was not of such importance as has been alleged, and considered that it should be possible to obtain with deep X rays all the results which can be obtained with radium. Of the latter, however, he had no experience, as there is little or no radium in Germany. He described two cases of carcinoma of the stomach which he considered had been cured by X rays and 12 cases of carcinoma of the oesophagus, four of which had remained well over a considerable period.

After the lecture we were entertained at lunch by Prof. Schmieden and met several members of his staff including Dr. Herbert Peiper, his first assistant, who has specialised in neurological surgery and carries out all the cerebral work in the clinic. We also met Dr. Joseph Wirth, medical superintendent of the hospital, who told us something of its organisation. It is a public hospital, with 2500 beds and is supported entirely by the State. Of these beds only 350 are allotted to the Academic Surgical Service over which Prof. Schmieden presides.

The afternoon was devoted to a visit to the X ray department under the control of Prof. Holfelder, reputed to be the finest in Germany. It is accommodated in a building especially erected for the purpose, and it was equipped in a manner which excited our envy and admiration. The room for deep X ray therapy, in which we were chiefly interested, was divided into two large apartments, each containing a battery of three "cannons" containing Coolidge tubes. The high tension current was supplied from a stabili-volt apparatus by Siemens-Reiniger-Weiss, working at a pressure of 300,000 volts. Each cannon was a lead tube some 6 feet long by 18 inches in diameter, with a wall an inch in thickness, but this enormous mass of lead was so beautifully balanced that it could be rotated by a touch into any position, whilst vertical adjustments were controlled by a small motor. It is impossible to describe the details of the apparatus, but it was so easy to manipulate that a nurse could adjust it single-handed, whilst by a most ingenious system of interlocking the screening and exposure were made practically fool-proof.

The diagnostic equipment, arranged on somewhat similar lines, was very complete and included a Titanos transformer by Koch and Sterzel, with an output of 100 milliamperes.

The Institute was fully equipped with ultra-violet and diathermy apparatus, but one of its most attractive features was a small lecture theatre surrounded by illuminated screens for the demonstration of films. The screens, which covered the greater part of two walls, were occupied by the current X rays of patients in the hospital and were demonstrated to us by Dr. Pansdorf, who is in charge of the diagnostic section. For absolute perfection of technique we have never seen anything to rival them, and as they covered almost every branch of radiography they were a striking tribute to the efficiency of the department.

On Thursday morning we again met in Prof. Schmieden's operating theatre where we saw two operations—an abdomino-perineal excision of the rectum for carcinoma in a woman of 25, and removal of the gall-bladder for gall-stones. The former was carried out on orthodox lines with a left inguinal colotomy and removal of the coecum. Owing to the careful preliminary ligation of the mesenteric vessels there was remarkably little bleeding. In the gall-bladder case, access was obtained by an oblique incision in which the upper part of the right rectus was divided. In this case, as in all the other abdominal cases which we saw, we were very much struck by the facility with which the liver could be

arranged for private patients, and the maternity and child welfare committee assist in defraying the cost of the confinement of poor mothers in this ward. Out of 24 samples of milk examined biologically, one, produced in the rural area outside the borough, was found to contain tubercle bacilli, and the veterinary examination of the dairy herd was being carried out at the end of the year. In addition three milch cows were reported under the Tuberculosis Order, two being found post mortem slightly affected, and the other in a fairly advanced stage of the disease. Five prosecutions were undertaken for added water in milk; two were successful but three, where the percentage of added water was given as 9.4, 5.6, and 5.8 respectively, were dismissed on payment of costs. In the case of two of the monthly examinations of the water-supply the public analyst reported that in his opinion chlorination had not been carried sufficiently far.

The closets have nearly all been converted to the water-carriage system, the accommodation being, at present: clean water-closets 8474, waste water-closets 264, pail-closets 19, and privies 94. Town-planning work has been taken over by the East Cheshire Town Planning Committee. The new houses erected numbered 129, 108 of which were State-aided, 74 being municipal. There are 17 slaughter-houses in constant use, ten being registered and seven licensed; and the Health Committee rejected an application for the erection of a new one.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 12TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox 423 (last week 457); scarlet fever, 2226; diphtheria, 1432; enteric fever, 85; pneumonia, 1296; puerperal fever, 68; puerperal pyrexia, 107; cerebro-spinal fever, 15; acute poliomyelitis, 2; acute poliomyelitis, 3; enteric fever, 13; typhus fever, 1; dysentery, 5; ophthalmia neonatorum, 123. No case of cholera or plague was notified during the week.

The case of typhus was the second within a fortnight to be notified in the metropolitan borough of Shoreditch, but on inquiry at the Western Fever Hospital—to which, as we reported last week, the mother and daughter were admitted for observation—we learn that their infection proves to be glandular fever (infectious mononucleosis). A niece of the elder patient is in St. Bartholomew's Hospital suffering from the same condition.

The number of cases in the infectious hospitals of the Metropolitan Asylums Board on April 15th–16th was as follows: Small-pox, 660 under treatment, 31 under observation (last week 682 and 23 respectively); scarlet fever, 2105; diphtheria, 2785; enteric fever, 27; measles, 1067; whooping-cough, 65; puerperal fever, 29 (plus 17 babies); encephalitis lethargica, 120; poliomyelitis, 2; "other diseases," 25. At St. Margaret's Hospital there were 17 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there were 2 deaths from small-pox, 4 (1) from enteric fever, 122 (63) from measles, 10 (5) from scarlet fever, 42 (4) from whooping-cough, 43 (8) from diphtheria, 44 (11) from diarrhoea and enteritis under two years, and 60 (9) from influenza. The figures in parentheses are those for London itself.

The deaths provisionally classified to small-pox were assigned to Camberwell (Met. Boro.) and Leeds. The deaths from enteric fever outside London were reported from West Ham, Plymouth, and Leicester. Fatal cases of measles were widely distributed with larger numbers at Salford, 11; and Manchester, 6. (Glasgow reported 10.) Whooping-cough claimed 5 victims each at Birmingham, Liverpool, and Manchester. Diarrhoea accounted for 6 deaths at Liverpool, 4 at Birmingham. No more than 3 deaths were attributed to influenza in any large town.

The number of stillbirths notified during the week was 301 (corresponding to a rate of 41 per 1000 births), including 70 in London.

FATAL CASES OF SMALL-POX.

The fatal case of small-pox reported in last week's return from the metropolitan borough of Stepney was that of a woman of 66, the widow of a dock labourer, who had been for many years an inmate of the South Grove Institution. The disease began on March 22nd; the rash appeared on the 25th, when she was removed to the Joyce Green Hospital, where she died on April 2nd. We learn from Dr. J. M. Browne, acting medical officer of health, that the death certificate was filled up thus: 1. (a) Heart failure; (b) card. vasc. degen. 2. Small-pox (vacc. in infancy); no P.M.

AUSTRALASIA.

(FROM OUR OWN CORRESPONDENT.)

Training of Crippled Children.

THE Rotary Club of Sydney adopted as its major activity for 1928–29 the educational and vocational training of crippled children. A committee was formed to make a survey of the Sydney metropolitan area to ascertain the number of crippled children and to arrange for clinics. Their inquiry showed a definite need and justification for such work. While skilful orthopaedic surgeons were available, and hospital facilities, the educational opportunities were woefully lacking. The proper sequence, it was agreed, was first to locate the crippled child and lodge him in appropriate quarters; then to provide proper medical and surgical attention, and only after this to adopt any comprehensive educational measures such as vocational training. It was estimated that two or three thousand crippled children would be found in Sydney's population of roughly one million, and that 625 of these would require hospital care. In making recommendations the committee laid stress on the importance of avoiding any disturbance of the relations between the private physician and his patients. "It is unfair, unwise, and unethical," they say, "to embark upon any activity which fails to fully recognise the importance of proper measures to protect the incomes and livelihoods of the medical men concerned."

The New South Wales Society for Crippled Children has now been formed to carry on the work started by the Rotary Club, and has formally taken over the funds, record books, office staff, and equipment of the Crippled Children's Service Committee. Clinics have been established for advising patients whether treatment is likely to be of service, and for directing them to the best means of obtaining treatment. They do not carry out treatment themselves, recognising that the existing services are able to cope with all cases.

Post-graduate Work in Sydney.

Post-graduate instruction in Sydney has hitherto been wholly inadequate. Occasionally courses have been given by various bodies, but no systematic organisation has been attempted. In Melbourne a special post-graduate committee has been conducting courses for some years with great success, and has each year invited over-seas lecturers to give courses on special subjects. The activity and success of the Melbourne committee has been in marked contrast to the apathy in Sydney. The New South Wales branch of the British Medical Association has now taken steps to remedy this unsatisfactory state of affairs, and has formed a Post-graduate Work Committee. A general revision course for country practitioners is to begin on May 24th, and it is hoped that courses in special subjects can be arranged.

Man-eating Sharks.

Not long ago a young man bathing off Middle Brighton Pier at Melbourne was carried off by a shark, and his fate has led to an investigation of protective measures by the Surf Life-saving Association. At Melbourne this is the first death of the kind since 1876. Bathing in Tasmania is said to be free from all risk; in Sydney, on the other hand, there have been accidents of the kind sporadically every

season, and they are also reported from Queensland. Considering the millions of bathers who throng the various surfing beaches each summer, the risk to any individual is infinitesimal, but in certain places it has been thought worth while to build shark-proof fences on the beaches. Whilst harbour bathing has always been known to be dangerous on account of sharks, it is only within comparatively recent years that bathers on the surfing beaches have been attacked.

Not very much is yet known of the habits of the man-eating sharks. Recently a company has been formed known as the Marine Industry Limited, for the purpose of catching sharks and treating them for commercial purposes, and there is no doubt that its work will considerably add to our knowledge of the types of shark present, their location, and their habits.

This company has been operating in the Port Stephens district, and has found that the following sharks are the most common in their order of prevalence: the whaler (*Carcharhinus macrurus*), the grey nurse (*Carcharias armatus*), the tiger shark (*Galeocerda tigris*), and the white shark (*Carcharodon carcharias*). Actually the shark most often caught is the Port Jackson shark (*Heterodontus philippi* and *Gyrodontus galeatus*), whilst carpet sharks (*Orectolobus derisi*) and wobbegongs (*O. maculatus*) are almost as prevalent as the grey nurse.¹ The Port Jackson, the wobbegong, and carpet shark and also the seven-gilled shark (*Notothynchus pectorosus*) are not regarded as man-eaters. The whaler, grey nurse, tiger shark, the white shark, and also the hammer-headed shark (*Sphyrna zygaena*) and blue-pointer (*Isurus glaucus*) are all held to be dangerous to man. It is interesting to note that shark attacks are unknown in American waters, although the white shark, the hammer-headed shark, and a species closely allied to the Australian grey nurse, occur there.

There is some difficulty in getting correct information about the type of shark concerned in any particular accident, owing to the rapid movements and the absence of competent observers. Attacks appear to be more frequent in the early morning and late afternoon, and particularly on dull days. It has been stated that mating time is the dangerous period—i.e., about February and March. Lone bathers are particularly liable to attack. As a rule the victim is brought ashore, but even then the death-rate from shark-bite is very high. The wounds are of two kinds—those actually caused by the bite, and others caused probably by the impact of the body and the fins. Most of the wounds have been on the legs; either the foot and part of the leg has been completely severed, or large parts of the thigh or buttock have been bitten off. Some idea of the power of the bite can be gained from a case in which a large portion was removed from the loin at the level of the crest of the ilium; part of this bone was taken in the bite, the bone being removed flush with the soft parts. The hand and forearm have been taken off, but this does not often happen. Bites actually on the body are uncommon on those admitted to hospital. Of those bitten, many die very rapidly from hemorrhage, and those who survive this generally die either from shock or gas gangrene. In almost all those who have recovered, the bite has been on a limb which has required amputation later. Amputation of the limb or complete excision of the bite, where amputation is not possible, seems to offer the best chance of recovery.

It has been suggested that the patient should be kept at the beach casualty room, until shock has been treated, before removal to hospital. This presents many difficulties, and the Surf Life-saving Association holds that expert medical and nursing attention in hospital should be secured as soon as hemorrhage has been dealt with. This should be done at the water's edge, and the patient should be transferred to hospital as soon as his condition will allow of it. The hospital should be previously notified so that immediate arrangements can be made for blood transfusion.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

An Epidemic of Trichinosis.

AN outbreak of trichinosis in Stuttgart, Württemberg, has been traced to bear's ham served to the guests of a restaurant. The ham was that of a polar bear belonging to a small circus which did not prosper and was therefore dissolved. The proprietor of the restaurant bought the bear, which was apparently sound, and put bear's ham on the bill of fare. The meat was very much enjoyed by his clients, but those who had eaten of it complained some time afterwards of severe muscular pain; fever developed, and they had to be taken to hospital, where the nature of the disease was eventually ascertained. Eventually more than 70 people were taken ill, and ten of them died, including the proprietor of the restaurant and his wife. There is some astonishment among the public that it is possible to have such an epidemic of trichinosis, which has almost disappeared in Germany as a result of the careful meat inspection. It is stated, however, that there is a gap in the law, in that game is not liable to examination, and the proprietor of the restaurant was thus within his rights to sell the meat without inspection. According to veterinarians bears often suffer from trichinosis, and though the flesh of these animals is very seldom eaten in this country, meat inspection should be extended to it.

Medical Education.

The Berlin Medical Chamber has been discussing the reform of medical study and of medical examinations. This subject is of interest to medical men in general, since the overcrowding of the profession is partly due to the unsatisfactory system of examination. Dr. His, professor of clinical medicine and head of the first medical clinic of the university, said he thought medical students should have enough knowledge of Latin to enable them to understand the terms which are international and have partly been used for centuries. Formerly only students coming from a public school where Latin and Greek are taught were admitted to medical study, but for some time pupils of schools without classical instruction have been able to matriculate as medical students. Prof. His also spoke against the proposal to separate medical study from the university, and set up special medical schools. Examination and study, he said, should be arranged according to the requirements of general practice and special training should be reserved for the period of assistantship after qualification. Medicine, surgery, and obstetrics should be the nucleus of study and examination, and time should be devoted to the study of special branches only so far as they are of use to the general practitioner. The medical students should be trained in nursing too. In the first term he should be taught physics, chemistry, and biology, but in separate courses and not alongside students of chemistry and physics whose instruction is, of course, to be more extensive. An examination will follow, and if a student shows that he has no gift for natural science he should not be allowed to go on with his studies. After the second term an examination in anatomy and in physiology should be held, with similar consequences, and after this second examination seven terms of clinical study should follow. During the university vacations medical students should work as dressers and clinical clerks, and the year's practical work in hospital should be passed before and not (as hitherto) after, the final examination. In this way the examiner would be in a position to say whether the candidate had a practical and not only a theoretical knowledge of medicine.

Inguinal Lymphogranulomatosis.

Dr. Frey lately read a paper before the Berlin Medical Society on lymphogranulomatosis as a venereal disease. The symptoms, he said, are a torpid swelling of the inguinal glands, taking origin

¹ Roughley, T. C.: Austral. Museum Magazine, 1926, III., No. 5.

from an erosion of the genitals. The venereal nature of the disease is proved by the fact that infection is often caused by sexual intercourse, the partner showing the same symptoms some time later. The diagnosis, according to Frey, is established by cutaneous reaction produced by attenuated bubonic pus as antigen. For the treatment antimonial preparations are recommended.

An Institute of Radiological Research.

An institute of radiological research has been opened in Berlin in connexion with the medical faculty of the university. The head of the new institution is Prof. Friedrich, who, at the same time, has been appointed ordinary professor of medical physics in the university. The premises were opened in the presence of the Minister for Education, who said that the Government intend also to set up an institute of radiotherapy, and that this would be done as soon as the necessary funds were available. The buildings include a physical department with the most modern röntgen and high-frequency apparatus, a biological and a chemical department, a lecture room, and a laboratory for testing radium preparations used in public hospitals.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Recuperated Bath Water.

THE conduct of a thermal establishment at the popular resort of St. Nectaire has been the subject of legal investigation. The place was bought some years ago by a Dutchman named Van Gerdinge, who with his family undertook its whole management. Some time later it was rumoured that the bathing plant had been reconstructed by the new owner so as to heat up again the bath water used by previous bathers, an economical arrangement which did not conform to the precise requirements of modern hygiene. On inquiry the police found a secret plant for reheating the bath water, and the proprietor and his son were tried last week at the local police-court and sentenced to three months' imprisonment with an additional fine of about £1500. Compensation was awarded to the victimised clients to an amount varying between £12 and £90 each. An expert has been nominated by the Court to assess the amount of indemnity payable to the health resort.

Social Insurance.

Deputies being now quit of the Budget have set to work on the social insurance law. Both Chambers are due to rise shortly, and it is not quite certain that the law will have passed all its stages by the first of July, the date promised when the measure was postponed last January. The desired concessions to professional ethics have been made on all points in deference to pressure from the leaders of the profession.

An X Ray Martyr.

Dr. Robert Chaperon has died in Paris after a long illness occasioned by professional exposure to X rays at the Hôpital Broussais, where he was radiologist and assistant in electroradiology to Dr. Laubry. Two days before his death he was visited by the new Minister of Public Health, accompanied by members of the hospital staff, who conferred on him the gold medal of the Assistance Publique. It is understood that his memory will carry the insignia of the Legion of Honour which was not awarded to him in his lifetime.

ENLARGEMENT OF BROOK HOSPITAL.—This transferred hospital at Shooters Hill, Woolwich, is to be enlarged by the London County Council at a cost of £50,000, one-half of which will be absorbed by a nurses' home. When this hospital is full 227 nurses will be required.

"Audi alteram partem."

A UNIVERSITY DEGREE FOR THE GENERAL PRACTITIONER.

To the Editor of THE LANCET.

SIR,—General practitioners of the British Empire will welcome the practical results of the findings of the Post-graduate Medical Education Committee. It must surely be fully realised that the main object of the medical student is to get through his examinations. Those who can afford it—for the cost of the medical curriculum is, speaking generally, a severe strain on the finances of parents—may be able to spend further time and money in obtaining higher qualifications, but everyone is aware that at the time of qualification one knows very little, if anything, of practical medicine. It is only when one encounters practical problems, after qualification, that one begins to learn medicine in its various branches. This fact, although sufficiently obvious, has not been fully appreciated by the authorities, and concentration on the encouragement of practitioners—who after all, are treating the great proportion of the sick population—will result in the greatest benefit to medicine as a whole.

Registered medical practitioners will therefore welcome with pleasure the fact that the Ministry of Health is seeking, in addition to other great authorities, the support of the University of London and will rejoice that, at last, the case of the general practitioner is beginning to be considered, and the importance of encouraging his further education is being realised. In this scheme the University of London can, if it so desires, play a unique and important part in encouraging practitioners to continue to be students of medicine. It can, in a broad and tolerant spirit—by granting an M.D. Degree to registered medical practitioners of the British Empire of approved standing—i.e., those who have contributed, e.g., in their field of general practice, to clinical research, and who are of, let us say, at least ten years standing, and who have, after a course of study at the post-graduate medical school, passed a required examination suitable for a general practitioner—do much to make the post-graduate hospital a medical metropolis of the British Empire, and encourage practitioners to continue to remain students of medicine.

In this way the University of London can share in the scheme and feel that it is—by granting its degree to a registered medical practitioner of approved professional standing and attainments who has studied in its post-graduate medical school—assisting, practically and in a peculiar way, in the encouragement of post-graduate medical study by general practitioners.—I am, Sir, yours faithfully,

April 16th, 1930.

M.D., M.R.C.P.

DISTRIBUTION OF TYPHUS VIRUS IN THE BLOOD.

To the Editor of THE LANCET.

SIR,—In a recent issue you called attention to the important section in the report of the Medical Research Council dealing with the virus diseases. On p. 19 of that report it is stated that it was shown, before the war, that the virus of typhus does not float freely in the blood, but is contained in the white corpuscles. That was the conclusion originally arrived at by Nicolle, but it does not hold now. It was shown first by Kusama and subsequently by Bacot and Ségal that the virus is contained not in the leucocytes, but in the blood-platelets. And Bacot, with his brilliant technique, was able to produce the infection of lice per anum with platelets proved by the

subsequent occurrence of the typhus "Rickettsia" bodies in the gut. I am under the impression that Nicolle has since agreed with this determination of the true distribution of the virus in the blood. It is important to point out the above fact, not only in justice to the late Mr. Bacot's work, but because of its significant bearing in relation to the pathology and aetiology of the disease. Typhus is particularly a derangement of the reticulo-endothelial system, and it is from certain cells with this ancestry (megakaryocytes and monocytes), both of which are macrophagic, that the platelets are produced.

Incidentally, there is another rather misleading statement on the same page. Dealing with Dr. Andrewes's work on the in-vitro "cultivation" of a virus, the report says: "It can be proved that in a cultivation of this kind, the virus actually multiplies itself." That is, to my mind, exactly what has not been proved. As I pointed out in a recent letter to your columns (Jan. 25th, p. 211), the increase of a virus in tissue-cell "cultures" is by no means the same thing as multiplication, because there is the probability that the additional quantity of virus is produced by the living cells themselves and not actually by the virus, which is to be regarded—again, I say, most probably—as non-living and of the nature of an abnormal blood-digestive enzyme. Convinced as I myself am, from my studies of the nature of various inclusions, of the general truth of this theory, I have never said it is proved. Progress in science is hampered by saying that a thing is proved when such is not the case.

I am, Sir, yours faithfully,

H. M. WOODCOCK.

April 16th, 1930.

A MANUAL OF FEVERS IN INDIA.

To the Editor of THE LANCET.

SIR,—In the issue of THE LANCET for Jan. 25th I notice a review of my book "Infectious Diseases and Other Fevers in India." I find that it is no review at all, and instead of pointing out whether the book is useful or not for whom it is intended, your reviewer starts criticising the whole material in an unfair spirit, setting out only the defects. Also he should realise that the book is not meant for himself or his like, and students in Great Britain, but is meant for our students and practitioners here. The discussion of yellow fever is included at length because of the ever-present danger of its being introduced in India after the construction of the Panama Canal, and it is frequently mentioned by the Government for their special works, such as the ruinous Back Bay reclamation, so as to provide isolation space. Also we have got in this hospital a special screened ward kept reserved for it. It is from this point of view, as well as from the similarity of the preventive measures (which form the main bulk of that chapter) to those of malaria (as regards mosquitoes), the most common type of fever prevailing in this country, that so many pages are devoted to it rather than to undulant fever, which is hardly noticed in this country. As a matter of fact it is by mistake only that my book was sent by the publishers to reviewers outside India, as we know that our point of view will never be considered by the people abroad, and specially in England.

I am, Sir, yours faithfully,

P. T. PATEL, M.D., M.R.C.P. Lond.,

Medical Superintendent, City Isolation Hospitals, Bombay, India.

March 8th, 1930.

HIGHLANDS AND ISLANDS MEDICAL SERVICE.

To the Editor of THE LANCET.

SIR,—Owing to the exhaustion of the Highlands and Islands (Medical Service) Fund, Parliament recently authorised an increase to the previous inadequate Treasury grant in order that the recommendations of the report of the Dewar Commission of 1912 may be

carried out. One of the most important recommendations of that report was the institution of a contributory superannuation scheme for the medical officers of the above Service in the poor and remote single-practice areas where income from private practice is negligible and the medical officer's work is almost altogether national work. It is said that the late Board of Health had such a scheme considered, but that at the time the scheme, for financial reasons, could not be put into force. It is to be hoped, now the financial conditions are adequate, that a satisfactory scheme for superannuation of the medical officers will be granted by the Department in the interest of the efficiency of this essential medical service.

I am, Sir, yours faithfully,

VIATOR.

April 23rd, 1930.

Obituary.

FRANCIS LEY AUGUSTUS GREAVES, O.B.E.,
F.R.C.S. Eng.

Mr. Frank Greaves had recently tried to curtail some of his professional activities on account of his health, but the news of his death on April 18th came as a shock to a wide circle of friends and medical colleagues. He was actively engaged in hospital and consulting practice until a few weeks ago.

Born at Derby 55 years ago, he was the son of a medical man, Dr. C. A. Greaves, who held the post of honorary physician to the Derbyshire Royal Infirmary. He entered St. Thomas's Hospital, and after a distinguished career as a student qualified as M.R.C.S. in 1897, and was appointed house surgeon. In 1898 he became assistant house surgeon, and in the following year house surgeon to the Derbyshire Royal Infirmary, which institution he was still serving at the time of his death. In 1902 he obtained the Fellowship of the Royal College of Surgeons and was appointed honorary surgeon to the Infirmary. Three years later he inaugurated the ear, throat, and nose department, acting as honorary surgeon in this specialty, and also as honorary surgeon in the general surgical departments. As an officer in the Territorial Force he went on active service at the outset of the war; and later his surgical abilities were fully employed as acting lieutenant-colonel in charge of surgical divisions of the 26th and 74th General Hospitals in France.

Apart from his work at the Derbyshire Royal Infirmary, Greaves was consulting aural surgeon to the Derbyshire Hospital for Sick Children and consulting surgeon to the Whitworth Hospital, Darley Dale, and to the Ripley Cottage Hospital. He had a large consulting practice, both as a throat specialist and in general surgery, for more than twenty years, and was held in great esteem by the profession in and around Derby. His hospital work was of a high standard; his outstanding experience being in the surgery of the thyroid gland and the treatment of fractures. He was always an enthusiastic worker for the Derby Medical Society, and his life and work did much for the scientific side of medicine in the locality. At the time of his death he had just finished a year as chairman of the Derbyshire Division of the British Medical Association.

In 1906 Mr. Greaves married Constance May Rice, who, with their son, survives him.

ST. BARTHOLOMEW'S HOSPITAL NEW SURGICAL BLOCK.—This building will probably be completed during May. The ground floor is already finished and equipped, and was last week opened to the inspection of anyone who applies for a ticket. In the male ward there is an exhibition illustrative of the progress of surgery from the earliest times to the present day. Among the exhibits are instruments found at Pompeii, which bear a remarkable resemblance to some of those now in use.

Notes, Comments, and Abstracts.

ABSINTHE AND ABSINTHE DRINKING IN ENGLAND.

By C. W. J. BRASHER, M.D.,

FORMERLY MEDICAL SGT., RENDLESHAM HALL, SUFFOLK.

MANY readers of this journal may regard an article on absinthe and its dangers as superfluous, being unaware that this liqueur, of which the manufacture and sale have been prohibited in France, Belgium, Switzerland, Italy, Germany, and Bulgaria, is still manufactured and exported to England. I have been informed by a member of an exclusive London club that when a cocktail is ordered it is customary to inquire whether a "spot" shall be added—that "spot" being absinthe. Another London clubman states that "the cocktail 'with a kick in it' is often ordered by the more hardened cocktail drinker" and that the "kick" is obtained by the addition of an extra quantity of the basic spirit (gin, whisky, brandy, or rum) of the cocktail or of a variable amount of absinthe. A third patient states that "when in my club a cocktail is ordered, the waiter inquires 'with or without?'—i.e., with or without absinthe." The names of several brands of absinthe, vermouth, and chartreuse (both the latter liquors containing essential oil of wormwood) appear in the current price lists of many of the large London stores and wine-merchants.

Consumption of Spirits.

While the question of total abstinence versus moderate drinking of alcohol remains undecided, the majority of responsible men and women will agree that the consumption of wines and beers of low alcoholic strength is preferable to that of spirits and liqueurs. Many writers have regretted the gradual conversion of the United Kingdom from being a beer, cider, and wine-drinking nation to one in which the annual production of British distilled spirits rose from 10,372,000 proof gallons in 1810 (the first year in which complete returns were available) to 59,246,000 proof gallons in 1900. The population in 1810 being (approximately) 16 millions and in 1900 (approximately) 40 millions. In this ratio, the production in 1900 should have been 25,930,000 gallons, or 33,316,000 gallons less than the total production in that year.

For many centuries, before the introduction of tea, coffee, and cocoa, home-brewed or "small" beer, of low alcoholic strength was the national beverage of England. There was no native production of distilled spirits corresponding to the "usquebaugh" or whisky of Scotland and Ireland, although brandy was introduced into England in the reign of Henry VIII., and whisky was distilled by Irish settlers in Pembrokeshire in the latter part of the sixteenth century. With the growth of the West Indian slave-trade, rum was introduced into the larger English seaports, especially Bristol and Liverpool. It was adopted as the regulation liquor in the Royal Navy in the reign of Charles II., and it became a popular drink as well as a favourite family medicine.

An increased consumption of spirits followed the Napoleonic Wars. The Army learned to drink brandy in France, and it became a fashionable beverage among men of the Regency period. The popularity of brandy continued until it was superseded, firstly by Irish and then by Scotch whisky during the last quarter of the nineteenth century. Consequently, the consumption of spirits increased rapidly, but it was almost entirely confined to the male sex. The numerous references to brandy and water in the works of Dickens and Thackeray indicate the popularity of this spirit. Women took it medicinally, but social and convivial spirit-drinking among women and girls was unknown.

The habit of drinking spirits of high alcoholic content grew quickly, until many persons drank brandy, whisky, rum, or gin without dilution. Liqueurs were introduced from the Continent, and were drunk usually undiluted, although the alcoholic content of the weakest liqueur—aniset—*is* 27 per cent. by volume.¹ At the same time port and sherry were "fortified" for the British market by the addition of rectified spirits in order to satisfy the increasing national desire for higher alcoholic content.

In the compilation of Inland Revenue statistics it has been usual to group according to the mode of manufacture—i.e., by fermentation or distillation—various alcoholic liquors, regardless of the percentage of contained alcohol; but many Governments have come to recognise the importance of the alcoholic content and consequently prohibit the manufacture and sale of liquors of high alcoholic strength.

On Nov. 15th, 1918, the Belgian Government "prohibited the manufacture and sale or keeping for sale of distilled alcohol (spirits) or wines with more than 15 per cent. alcoholic strength and beers or beverages with more than 8 per cent. of alcohol; except alcohol for medicinal, scientific, and industrial uses." "Other Acts (August 20th, 1919) followed by Ministerial decree (Sept. 10th, 1919), increased the tax on alcoholic liquors in order (a) to secure increased revenue, and (b) to combat alcoholism by prohibiting absolutely the consumption of spirits in all places accessible to the public."²

The introduction into Great Britain of Continental liqueurs was followed later by that of "cocktails" from America, and, since the war, the latter have become increasingly popular among young men and women of the upper and middle classes. Prof. W. E. Dixon's article "Cocktails and their Effects"³ received warm commendation in the press, but his warnings seem to have had little effect. "Cocktail parties" have become very popular among society women of all ages, and I have been told by several patients that many young men and women ask for a "spot" of absinthe in a cocktail, doubtless often in ignorance of its composition.

Nature of Absinthe.

"Absinthe," says the *Encyclopædia Britannica*, "is a highly toxic liqueur or aromatised spirit, the characteristic flavouring matter of which is derived from various species of wormwood (*Artemisia absinthium*). Among the other substances generally employed in its manufacture are angelica root, sweet flag, dittany leaves, star-anise fruit, fennel, and hyssop. The Swiss variety has a higher alcoholic strength than the French. The best absinthe contains 70 per cent. to 80 per cent. of alcohol. It quickly intoxicates, and its deleterious effects are more serious than those of other forms of alcohol. The wormwood acts powerfully upon the nerve centres and causes delirium and hallucinations, followed in some cases by idiocy."⁴

Oil of absinthe is also an ingredient of French and Italian vermouth, of chartreuse, and of a popular "bitter" aperitif.⁵ Although the manufacture and sale of absinthe were prohibited in Switzerland on July 5th, 1908,⁶ in Italy in 1913; and in France on March 16th, 1915,⁷ the sale of absinthe and of vermouth is unrestricted in England. The laws of Switzerland, Italy, and France are being infringed in order to manufacture these liqueurs for export to Great Britain. These laws were passed in all three countries in the face of strenuous and prolonged opposition on the part of manufacturers of the liqueurs in question. Each firm claimed that their special brand of absinthe was not only harmless but even had medicinal value. In Switzerland and in France these claims were supported by certain Ministers and senators.⁸ In Switzerland the opposition to the legal prohibition of absinthe was so strong (especially in the Cantons of Geneva and Neuchâtel) that in 1906 the Federal Department of Justice and Police appointed a commission of three professors—Dr. J. Gaule, Dr. A. Jaquet, and Dr. R. Weber.⁹ In their report this commission described minutely the manufacture of absinthe, as well as its physiological effects on animals and man. They found that the health of any community deteriorated rapidly when absinthe drinking prevailed. They quoted the following statement made by Colas and Gautier, two French supporters of the absinthe trade: "If, therefore, absinthe may be considered as more dangerous than other spirituous beverages, it is not because it is more toxic in itself, but because its particular flavour offers greater attraction to the drinker and leads him more easily to abuse."¹⁰ Gaule, Jaquet, and Weber stated: "Our personal experience leads us to the conclusion that there is, in effect, an analogy between the absinthe drinker and the morphinomaniac. There is no deception which either will not employ to satisfy their passion." The commissioners agreed with Leonidoff: "absinthe has become the most popular aperitif and, among certain drinkers, it is the only beverage."

Ledoux draws attention to another danger; Senator Borne, in defending the Pontarlier product, stated: "At Pontarlier, only the purest alcohol enters into the manufactures of absinthe—ethyl alcohol, 'spirits of wine' rectified alcohol. But on the other hand, there are absinthes made with impure alcohol." Rocques observes "Analyses of Alcohols and of eaux-de-vie." "It is probable and even certain that inferior alcohols are sometimes utilised for the manufacture of common products, principally of absinthes and of other liqueurs of which the very strong aroma can mask the taste of inferior alcohols."¹¹ This writer quotes several other authorities who state that methylated spirit and "denatured alcohol" are also employed in the manufacture of liqueurs.

Physiological Action of Absinthe.

Many eminent French and Swiss physicians—among others, Lancereaux, Legrain, Mairat, Combemale, Legendre, Sollier, and Féré—have studied the physiological effects of absinthe.

Lancereaux found 1229 alcoholics (901 of whom drank liqueurs) among 3192 patients suffering from tuberculosis; while Jaquet found 139 alcoholics among 252 tuberculous patients—i.e., 43.14 per cent. Dr. Mirman, Directeur de l'Assistance Publique, reported (June 27th, 1907) to the President of the Council that among 71,547 mental patients "interned" in 1907, 9932 became insane entirely or in part owing to alcoholism. Of these, 4882 (49.16 per cent.) drank absinthe or other "apéritifs."

Ledoux states that absinthe drinking in 1860 was confined to officers and men of l'Armée de l'Afrique; delusional insanity was common in that service, and was colloquially known as "le cafard." "These men on returning to France continued to drink their favourite beverage. Fashion and folly were the great disseminators of absinthism." While in France, in 1884, the consumption of absinthe amounted to 40,094 hectolitres, the figure rose in 1900 to 208,931 hectolitres—that is to say, that in 16 years the quantity of absinthe consumed increased more than five times. Ledoux shows that the incidence of insanity, idiocy, epilepsy, and tuberculosis in different regions of Eastern France corresponds closely with the percentage of the population addicted to absinthe. This statement is confirmed by reference to the statistics of rejection of Army recruits on account of tuberculosis or "feebleness of constitution." In one of his concluding sentences, Ledoux quotes the statement of 112 senators who presented a Bill for the prohibition of absinthe on June 22nd, 1908: "Absinthe causes insanity and crime, it predisposes to epilepsy and tuberculosis. Each year it kills thousands of Frenchmen; it makes man a beast, woman a martyr, the child a degenerate."

Lancereaux,¹⁰ who studied the problems of alcoholism for many years, was convinced that the essential oils of absinthe and of the other ingredients of the liquor were far more toxic than the alcohol which they were dissolved. He publishes as an official table of the Direction of Contributions for the years 1885-92 inclusive (the figures represent the volume of pure alcohol). These figures are for Paris and its suburbs only. They show that while the total increase in consumption of alcohol in Paris and its vicinity during that period was 4.00 per cent. only, the increase in the consumption of absinthe during the same period amounted to 124.6 per cent. Lancereaux believes that absinthe is far more insidious than ordinary alcohol. "Even the daily consumption of this liqueur is not fraught with danger if these persons could be satisfied with only one 'petit verre,' but this is far from being the case; the attraction possessed by this beverage drives the consumer generally to double and treble little by little the dose until the time comes when he cannot abandon it; thus is created a craving analogous to that for morphine, a desire almost as imperious as those of hunger and thirst." Lancereaux thought formerly "that limitation of the number of cabarets and an increase of the duty on liqueurs would suffice to arrest the progress of the evil, but since I learned better the attraction that this liqueur exercises on women even more than on men, on account of the essential oils which it contains, my conviction is that the only means of avoiding the danger is prohibition of the sale of this drink."

Many other passages from the works of eminent French authors might be quoted, but enough has been said to indicate that absinthe addiction begins insidiously and that, at first, the dose is very small. It is well known that some persons have so insatiable a craving for alcohol that they cannot be satisfied with ordinary beverages but have recourse to perfumes such as lavender water, eau-de-cologne, "extrait de violettes de Parme," &c.; probably not only for the effect of their concentrated alcohol, but also largely for the slightly toxic essential oils contained in the perfumes. Many of these perfume drinkers are women and some of them become addicted to morphine, heroin, and cocaine.

Cocktails.

Let it should be thought that Continental authorities have exaggerated the evils against absinthe, the following passage from Prof. W. E. Dixon's article on "Cocktails and the Effect" should be convincing: "A large percentage of cocktail drinkers are young men and young women, and they drink to lose their shyness, so that they may become bright and interesting, and it may be also partly in a spirit of bravado. These young people are usually not content with one drink; they often indulge in two or more, though the second has a much less pronounced action than the first—at least so far as the initial effect is concerned. Most drugs of addiction assuage the pangs of hunger and thirst. The person who habitually takes alcohol in excess has a poor appetite and rarely eats breakfast, though he may be fat and bloated in appearance. "The cocktail, on the other hand, improves appetite—at least, in certain abnormal conditions; this it does not by increasing hunger contractions, but by relieving temporarily the conditions which are producing inhibition of these contractions."

"All will agree that cocktails are utterly bad for the young. Their use injures the stomach and lays the foundation for a habit. Youth is the time when the drinking habit is acquired. Youth desires new sensations, strong emotions, and varied interests. Cocktails supply something of these for a very limited period; they do more than this, they cultivate the habit of drinking in a way and to a degree which, in my opinion, can be induced by no other type of beverage."

In a previous passage this writer shows that absinthe or vermouth are present in many popular cocktails, such as Martini, Bronx, and Manhattan. Absinthe (or vermouth) is added frequently to other cocktails.

Prohibition of Absinthe Abroad.

We have the evidence of distinguished French physicians that absinthe is as insidious as morphine and that the dose is increased rapidly in many cases, as in morphine and heroin addiction. Several French writers give details of crimes of violence committed by absinthe drinkers while suffering from delusions and hallucinations induced by absinthe. Murder and suicide were often attributable directly to this addiction.

It is certain that the Governments of France, Italy, Belgium, Switzerland, Bulgaria, and Germany had good reason for prohibiting the manufacture and sale of absinthe. In less than half a century, in the words of Lancereaux¹⁰: "It shows that the use of absinthes, confined formerly to Paris and its environs, has finished by invading the provinces and by spreading throughout France, where it produces the most serious results. . . . Let us be logical, therefore, if we seek, rightly, to protect ourselves from epidemic diseases, at home and abroad, do not let us permit to develop, under our careless eyes, a scourge more terrible than the most deadly epidemics. . . . The measures you propose, some will say, are too radical. You demand the suppression of important industries, which enrich the community and make it prosper. Fatal error! These trades, far from contributing to national prosperity, degrade and ruin it, because they are always causes of depopulation, of unemployment, and of demoralisation."

Although Lancereaux's appeal was published on Dec. 1st, 1906, and as we have seen, Switzerland prohibited the manufacture and sale of absinthe 19 months later (July 1908), France did not prohibit it until March, 1915, when the Great War had been waged for more than seven months, and the French national leaders realised that to save their country everything that made for inefficiency must be swept away. English writers have been astonished by the amazing rapidity with which France and Belgium have reconstructed their devastated regions. Can it be doubted that that progress would have been less rapid and satisfactory if there had been no prohibition of absinthe and of similar liquors?

The Importation of Absinthe.

If, as we have seen, six of the most progressive and patriotic of European nations have prohibited the manufacture and sale of absinthe and absinthe-containing beverages, the following questions arise: (1) Why is England indifferent to the dangers of absinthe? (2) How is it possible that absinthe should be shipped from the Continent to England?

1. England appears to be indifferent, largely through ignorance on this subject on the part of the general public and on the apathy of successive English Governments. Every year witnesses an increase in "that false spirit of laissez-faire which is not charity." The rising generation says, with Talleyrand "Avant tout, point de zèle." It tolerates if it does not approve the existence of every kind of evil. Enthusiasm for any subject is considered to be bad form.

In view of the French and Swiss evidence no responsible person could justify the continued importation of absinthe, even in small quantities. If, as Lancereaux has shown (vide supra) the increase in the consumption of absinthe in Paris and its vicinity in seven years (1885-92) amounted to 124.6 per cent. while the increase in the consumption of all alcoholic beverages during the same period was 4.00 per cent. only, there is no reason to suppose that a similar increase would not occur in England if fashion and folly should so ordain it.

It is quite clear, from the foregoing evidence, that absinthe has no possible claim to therapeutic value, but that on the other hand, it is extremely toxic and should be classified as a dangerous drug. The argument that the quantity is so small, that it is negligible, cannot be sustained. No vice claims a large number of victims in its initial stage. It begins insidiously, as absinthe-drinking commenced in France. If but once it obtains a foothold, "vested interests" will make the task of prohibition of absinthe as difficult as it was in France and Switzerland, where, as has been seen, the opponents of prohibition were numerous and powerful. In Switzerland these persons numbered 80,105 in an electorate of 368,105, or over a quarter of the electorate.

They had an actual majority in the cantons of Geneva and Neuchâtel.⁴ Legislation will not stamp out any trade which has the support of a strong and determined minority, the trade will be "driven underground" and carried on surreptitiously. There can be no doubt that a contraband trade exists, and may, at any time become formidable.

2. How is it possible that absinthe should be imported from the Continent to England? On Feb. 18th, 1930, the Secretary to the Treasury replied to a question by Mr. Leif Jones, M.P., concerning the amount and value of absinthe imported during the last nine years (1921-29). The reply is incomplete, inasmuch as "no separate particulars are available with regard to vermuth or absinthe-containing cocktails which are classified as 'wine' or 'liqueur cordial mixtures' and 'other preparations containing spirits' respectively."

The figures for imports of absinthe alone for the years 1921-29 are interesting for several reasons. The countries whence absinthe is consigned to England are (a) the Netherlands, (b) France, (c) Spain. According to the latest available information,¹ Holland is not an absinthe manufacturing country, and in regard to prohibition, Dr. R. Herod, of Lausanne, states that "absinthe is probably prohibited in Holland." It appears, therefore, that absinthe is exported from its country of origin to Holland for shipment to England. France still manufactures absinthe in spite of the prohibition of March 15th, 1915. The figures quoted by the Secretary to the Treasury show that whereas in 1921 only 24 "proof" gallons were imported from Holland, no less than 1112 "proof" gallons and 102 "liquid" gallons ("not to be tested for strength and therefore liable to a higher rate of duty") were imported from France. The third country from which England imports absinthe is Spain, a remarkable fact, for Spain has never manufactured absinthe, but it appears that it is not prohibited in that country. While the quantities imported into England from the Netherlands, France, and Spain vary considerably from year to year, rising from 1382 gallons in 1921 to 2550 gallons in 1923, it will be found that, speaking generally, when a large quantity is imported in one year from France, there is a reduction in the quantity consigned to England from Holland and Spain, and vice versa. The total quantity imported during this period of nine years from the Netherlands was 1582 gallons, while from France and Spain the figures are 6556 gallons and 6290 gallons respectively—i.e., the imports from the Netherlands are approximately only a quarter of those from France and from Spain. The total quantity imported from all three countries during the above period is 14,428 gallons.

A Public Menace.

As the majority of cocktail or absinthe drinkers take only a few drops of the liqueur in each glass (although Ledoux found that the quantity is increased rapidly in a considerable number of cases), it is obvious that this total quantity of 14,428 gallons indicates that a large number of persons drink this highly toxic beverage, and, at any time, if it became fashionable, the annual consumption of absinthe (instead of remaining practically stationary since 1927), would increase rapidly.

To argue that, because a comparatively small quantity of this deadly liqueur is consumed at the present time, the importation of absinthe may be ignored, is as dangerous as to suggest a similar course in regard to heroin or cocaine, and with less reason, because these alkaloids have their legitimate uses, whereas in the considered opinion of many eminent physicians in France and Switzerland, absinthe is not only valueless, but it is also a menace to the public health and the prosperity of the country.

The question of the prohibition of the importation and sale of absinthe in England should be considered on its merits, apart from any question of general prohibition of alcohol. Although the alcoholic content of absinthe is higher than that of any other beverage, it is evident that alcohol is not the toxic agent but the vehicle of the highly toxic vegetable oils which are responsible for the deleterious effects of absinthe.

MINIMISING DEATHS UNDER CHLOROFORM.

At a recent inquest, Dr. F. J. Waldo, the City and Southwark Coroner, stated that his figures showed a great decrease in the number of deaths during chloroform anaesthesia. Last year (1929) he had returned 15 verdicts of death accelerated by anaesthetics given for necessary operations. The patients all died in hospital, nine in the City and six in Southwark, the anaesthetic in 12 cases being ether, chloroform in two, and ethyl chloride in one. He was told that his suggestion that all ether administered should be tested and certified as pure by an analytical chemist, and kept in coloured bottles away from the light, was now carried out. On the other hand, his suggestion that coroners should coöperate with expert research workers in preventing anaesthetic deaths had so far not been put into practice.

COLLODION TREATMENT OF BOILS.

Dr. Walter J. Robbins¹ supports the use of collodion in the treatment of carbuncles and boils. He paints contractile collodion round and over the boil in a thick circular band by means of a saturated swab. Ten to twenty circular strokes are made, an opening being left in the collodion at the spot where it is desirable that the boil should point. A similar technique can be used for carbuncle; in either case it is important that the collodion should extend well beyond the outer limit of inflamed tissue and should cover as much of the surface of the swelling as possible. The lesion is then covered with a gauze dressing.

One of the chief advantages of the method, says Dr. Robbins, is that it appears to cause immediate relief of pain; as the skin contracts with the collodion the patient appreciates an improvement, usually within 30 seconds. Further, the surrounding skin is protected from infection, and no secondary crop appears round the primary focus. Incision is unnecessary, for the slough discharges itself as a rule within 24 hours; with carbuncles, however, sloughing may not occur for a week, and the pain is less readily relieved.

The method is not very satisfactory in situations where the skin is loose and the contour concave; in the axilla, for example, contraction of the skin only forms folds which exert no pressure.

FLIES PREFER WHITE LIGHT.

In a letter contributed by Pilkington Brothers, Limited, owners of glass works at St. Helens, Lancs, to *Nature* for April 5th, they refer to the preference of the house fly for white light over light of any other colour, red and yellow being especially deterrent. They quote an observation made by some jam manufacturers that flies avoided storage warehouses glazed with yellow glass, and when the communicating corridors were glazed with the same glass the flies disappeared from them also. Messrs. Pilkington intend to continue their experiments during the coming summer, and would be glad to learn of any similar experience.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—From April 28th to May 21th an intensive course in Diseases of the Throat, Nose and Ear will take place at the Central London Throat, Nose and Ear Hospital. From April 28th to May 30th there will be a comprehensive course in psychological medicine at the Maudsley Hospital, Denmark Hill. Besides lectures and demonstrations the various forms of clinical instruction at the hospital will be open to those enrolling. From April 28th to May 11th an afternoon course under the direction of Dr. Eric Pritchard will be given at the Infants Hospital, for not more than 16 entrants. This is designed to interest those engaged in infant welfare, and clinics will be held at various centres. From May 5th to 31st an afternoon course in dermatology will be given at the St. John's Hospital, comprising clinical instruction in the out-patient department and lectures at 5 p.m. on certain dates. Pathology classes can be arranged if desired. From May 12th to 24th an all-day course will be held at the City of London Hospital for Diseases of the Heart and Lungs. The other courses for May are one for the M.R.C.P. examination, comprising evening lectures and demonstrations in ophthalmology (May 13th to July 4th); an afternoon course in ophthalmology at the Central London Ophthalmic Hospital (May 19th to June 13th); and a course in diseases of children at the Hospital for Sick Children (May 26th to June 7th). This last requires a minimum of 12 entrants. There will also be an intensive course at the Queen Mary's Hospital, Stratford, from May 26th to June 7th, consisting of instruction in medicine, in surgery, and in the special departments. Detailed syllabuses of all courses may be had from the Secretary of the Fellowship, at 1, Wimpole-street, London, W.1.

Goulstonian Lectures

ENTITLED

THE SIGNIFICANCE TO CLINICAL MEDICINE
OF STUDIES INCALCIUM AND PHOSPHORUS
METABOLISM.*The Second Goulstonian Lecture in 1930, delivered before
the Royal College of Physicians of London
on March 13th*

BY DONALD HUNTER, M.D. LOND.,

FELLOW OF THE COLLEGE; ASSISTANT PHYSICIAN TO THE LONDON
HOSPITAL.

(WITH COLOURED PLATES.)

MR. PRESIDENT, FELLOWS, AND GENTLEMEN.—In this second lecture I desire first to direct your attention to certain experiments on the source of available calcium in the bones. Then I shall give an account of generalised osteitis fibrosa, stating the evidence for regarding it as due to hyperparathyroidism; and this in turn will be followed by a discussion of the effects of thyroxin and thyroid disease on calcium metabolism and of hyperthyroidism on the bones.

THE SOURCE OF AVAILABLE CALCIUM.

Studies of the metabolism during fasting¹⁰ show that the only fixed base which is drawn from body tissues is calcium. Thus, in starvation, sodium and potassium are retained, whereas calcium is excreted continuously from the bones. Is the mechanism which protects the sodium and potassium of the tissues sufficiently perfect to spare the bone in such a way as to leave its function as a supporting structure unimpaired? Certain experimental, radiological, and pathological evidence suggests that it is—suggests, in fact, that the spongiosa of bone acts as the storehouse of readily available calcium, and that the corticalls is at first spared in the process of calcium mobilisation.

This storehouse was first suggested to us by a series of experiments¹¹ on the treatment of lead poisoning. Aub and others¹¹ had shown that in chronic lead poisoning there was a striking parallelism between the metabolism of calcium and that of lead. Since lead is stored in the bones, we used parathormone in an attempt to secure its elimination along with calcium. Periods of treatment by parathormone were separated by intervals in which the patient was given a high calcium diet. The effect of the parathormone, when first given, was to cause a considerable excretion of calcium and of lead. On the second occasion the parathormone still produced its characteristic effect on the blood and more than doubled the calcium excretion, but it caused no excretion of lead. Now, since the patient had been removed from the source of exposure to lead, the inference from this experiment is that a readily available store of calcium contaminated by lead was depleted by the first treatment and was then replaced by a store of calcium during the period of high calcium intake. The second treatment then depleted the storehouse of calcium alone.

Effect of Parathormone on Bones.

Experimental observations on this problem were then made by Bauer, Aub, and Albright¹² working with rabbits and cats. Rabbits were injected with parathormone in increasing doses until they were receiving eight units per day. After 91 days they were killed together with controls. Each rabbit had

received approximately 500 units of parathormone and this had raised the serum calcium to about 15 mg. per 100 c.cm. Radiograms showed diminished density of the bones compared to the controls. The long bones, when sawn longitudinally and incinerated, showed that a great number of trabeculae of the spongiosa had disappeared, but no gross change could be seen in the corticalls. No histological observations were made, and these experiments should certainly be repeated in order, not only to discover whether the corticalls is intact as judged by the microscope, but also to determine the histological mechanism of the calcium depletion. According to histological evidence given below the mechanism of calcium depletion in hyperparathyroidism in man is a lacunar resorption by osteoclasts.

Effect of Calcium Content of Diet on Bones.

In cats changes in the spongy bone were brought about by diet alone. Five cats were placed on a high calcium diet consisting of milk, and four on a low calcium diet consisting of meat, fresh uncooked liver, and water. At the end of several months the left foreleg was amputated at the shoulder-joint, and the diets were reversed. After a similar period of time the animals were killed, thus allowing comparison of the humerus representing the period of high calcium diet with that of the period of low calcium diet. In this ingenious manner each animal served as its own control, and factors such as age, sex, activity, and season did not enter into the results obtained. These experiments showed that the trabeculae of spongy bone in adult cats are diminished on a low calcium diet and increased on a high calcium diet. The authors state that "no gross change in cortical thickness was demonstrable." The histological nature of this resorption and apposition of bone was not investigated.

Madder Experiments on Growth of Bones.

The next experiments take us back more than 350 years to Antonius Mizalduz,¹³ who first noticed the red colouration of the bones of animals fed with madder. This phenomenon was not known in England until the year 1736.

In the summer of that year a young surgeon, John Belchier, was entertained to supper by a calico printer in the City of London. His host was economical in his affairs and was in the habit of feeding his pigs on the madder-soaked bran from his dye-works. The result was that Belchier noticed that the pork served at table contained bone dyed red. Immediately afterwards he began experimenting on hens by forcibly feeding them on madder. One died after 10 days, and he found the bones, even those of the densest structure, stained deep red.¹⁴

The osteogenic function of the periosteum was discovered by du Hamel¹⁵ using this technique. He fed birds and animals alternately on madder diet and on ordinary food. He then demonstrated in the bones successive red and white layers or rings, the area formed latest being on the surface of the bone immediately under the periosteum. Only bone freshly deposited during the madder-feeding was stained bright red, though all bone might assume a pale pink colour.

In 1761 John Hunter used the method to prove his theory of bone growth. He fed growing animals on a madder diet for a month, then killed some of them, and kept the others for a further month on ordinary diet. Twenty preparations from these experiments are preserved in the Museum of the Royal College of Surgeons in London. Unfortunately the colour has faded from them, though some paintings¹⁶ have survived in better condition. Examination of these paintings, especially those of the mandible of a pig, fully bears out his statement¹⁷: "In the formation of a bone, ossification begins in a spot and gradually increases. By feeding an animal on madder, it is shown that, while bony matter is deposited on the outside of the bone, the absorbents are removing it

is shown by numerous osteoclasts in lacunae. In the manubrium, sternum, fifth right rib, and the other ribs beyond their focal expansions, formation of new bone is still less, and past and present resorption is greater. The corticallis has been extensively converted into substantial reticularis or has been reduced to a thin shell. The spongiosa has been reduced to a few attenuated "mouse-eaten" trabeculae. In the spongiosa of the upper end of the shaft of the humerus the trabeculae are reduced to a few small fragments. The depth of the osteoid zones is seldom greater than in the ribs of newly born infants and is never greater than in healing fractures in healthy adults.

Remarks.—There is a widely disseminated fibrosis of the type found in osteitis fibrosa. Coarsely fibred bone of the kind met is abnormal in an adult. It has, therefore, been formed during the disease. Further, coarsely fibred and lamellar bone were being formed at the time of death. Consequently, formation of bone is a feature of the pathological process. Abundant formation of new bone, however, is found in only a few focal areas, and here it has been preceded by complete, or almost complete, resorption of normal bone. In the skeleton as a whole resorption before, and at, the time of death preponderates enormously over apposition. Resorption is the characteristic feature. The depth of the relatively few osteoid zones that are present is within the limits of the normal. There is, therefore, no histological evidence of the cessation of calcification which characterises rickets and osteomalacia, nor of a removal of calcium by chemical solution. The reduction of calcium in

almost always confined to one parathyroid, whilst the others remain normal. It is true that Klemperer⁶⁶ has recorded a case of a parathyroid tumour associated with secondary carcinomatosis of bones. Here the skeletal decalcification seems to be a primary factor and the parathyroid tumour secondary, but this association must be rare and is possibly a coincidence. On account of Erdheim's investigations the question was repeatedly discussed at scientific meetings in Vienna.⁶⁷ As early as 1915 Schlagenhauser, at such a meeting, raised the question as to whether it was not justifiable to attempt the extirpation of a parathyroid tumour in cases of generalised osteitis fibrosa. Maresch supported this suggestion, but it was not until ten years later that Mandl⁶⁸ of the Vienna school first performed this operation. In view of the Vienna controversy, it is of great interest that he decided to explore the neck only after treatment by parathyroid transplants and parathyroid tablets had failed to relieve the symptoms.

Mandl's case. Generalised osteitis fibrosa with parathyroid tumour.—A man of 38. History of pains in pelvis and lower extremities for five years. Radiograms showed osteitis fibrosa of femora, pelvis, tibia, and ischium. Treated with parathyroid tablets. Spontaneous fracture of femur; union after two months. Became unable to stand or sit. Noticed heavy white deposit in urine. Four parathyroids from an accident case transplanted into abdominal wall. No improvement. It was therefore decided to explore the neck, though no tumour could be felt. Parathyroid tumour (25 by 15 by 12 mm.) removed at operation. Pains in

bones disappeared a few days after operation. White deposit in urine disappeared; urinary Ca excretion dropped to one-eighth the pre-operative value. Three and a half years later no pain. Walks with a stick. Serum Ca 13 to 14 mg. per 100 c.cm. No increase in density of X ray shadows of bones.

HYPER-PARATHYROIDISM.

We now turn to the biochemical aspect of this problem. In 1923 Du Bois⁶⁹ investigated the case of a man of 34 with the symptoms and signs of a generalised disease of the skeleton. Radiograms showed extensive decalcification of bones and a large cyst in the right femur. There was hypercalcaemia (serum Ca 15.3 mg. per 100 c.cm.) and a low blood phosphorus (plasma inorganic P 1.4 mg. per 100 c.cm.). Later Aub⁷⁰ investigated the same case, and found that the urinary output of calcium and phosphorus on a low calcium diet

FIG. 6.

Chemistry of the blood in hyper-parathyroidism: effect of removal of parathyroid tumour (Case 4). The blood was examined at intervals for nine months before and for two months after operation. The low calcium diet was that given during the investigation of the calcium balance. The high calcium diet was unweighed. It included four pints of milk daily, together with ice cream, cheese, and eggs. The presence of Chvostek sign has been charted as latent tetany.

the skeleton is due to the lacunar resorption of calcified bone by osteoclasts. (H.M.T.)

Relation of Parathyroid Tumour to Changes in Bone.

Meanwhile there was a difference of opinion as to whether the parathyroid tumour was primary or secondary in relation to the bone disease. Erdheim⁶⁴ himself defended the view that the disease of the skeleton was the primary factor, and that skeletal decalcification created such a demand for calcium that a compensatory hypertrophy of the parathyroids occurred. Against this is the fact that, in generalised osteitis fibrosa, hypertrophy or tumour formation is

was six to seven times greater than was found in normal individuals under identical conditions. He found that these changes in metabolism were equivalent to those of a normal individual receiving 100 units of parathormone daily. It was, therefore, reasonable to suppose that this patient was suffering from hyper-parathyroidism. Unfortunately, exploration of the neck revealed no tumour. However, it was the study of this case and the use of Aub's methods which led to the discovery of many cases of hyper-parathyroidism in the United States and in this country. Meanwhile in Germany, Austria, and Holland the work of Mandl was producing the same effect. Fourteen cases have now been published.

and I have recorded elsewhere¹² brief abstracts of these.

I will now relate a case¹³ which seems to me to place on a firm and irrefutable basis the idea that hyper-parathyroidism is a disease entity, and that the bone changes to which it gives rise are those of generalised osteitis fibrosa.

CASE 4. Hyper-parathyroidism. Hyperfunction of parathyroid tumour in a case of generalised osteitis fibrosa.—A married woman of 41 years (L.H. Reg. No. 40173, 1920).

Clinical history.—Nov., 1926: Pain in right knee followed by pain in lower part of back and in left buttock, left hip, and back of left thigh. May, 1928: Unable to walk without sticks, pain in lower spine and right knee. Oct., 1928: Attack of right lumbar pain with increased frequency of micturition. No history of having passed calculus or gravel. March 21st, 1929: Operation: Mr. Hugh Lett: Right kidney explored. Pelvis enlarged. No obstruction found. No calculi. Nephropexy performed. July, 1929: Patient weak and with difficulty aided by sticks. Sept., 1929: Symptoms worse. Constant pain in lower part of spine and tenderness of forearms and shins on pressure. Nov. 10th, 1929: Patient twisted her left ankle, causing a spontaneous fracture of the neck of the left femur.

Past history: Four children alive and well, one died at four weeks. No miscarriages. In each case labour was normal. No family history suggesting disease of bones.

On examination: Nov. 20th, 1929: A thin, poorly built woman. Calvaria normal size and contour. Sclerotics white. Lenses normal on examination by slit-lamp. Hearing normal.

Double dentures. Tongue clean. Mucous membranes normal colour. No thyroid enlargement. No tumour felt in neck. Heart and lungs normal. Blood pressure 140/90. No hypotension of muscles. No abnormality in nervous system. Trousseau and Chvostek signs absent. Shortening and eversion of left lower limb. Great pain on any attempt to manipulate left hip. Pressure upon the shafts of the long bones caused pain. On squeezing the hand there was pain in the heads of the metacarpals. In addition there was a smooth, firm, slightly tender swelling 4 by 1½ cm. in the lower end of the right ulna.

Urine: Cloud of albumin. Deposit: leucocytes. Blood: Bleeding time and coagulation time normal. Wassermann reaction negative.

Radiograms of bones: Greatly diminished density of shadows of all bones examined. This is emphasised by contrast with the bones of a control subject of the same age, sex, and build exposed simultaneously on the same negative. The sacrum, iliac bones, and right ulna (Fig. 5) are especially affected. Pale cyst-like areas, some of them trabeculated, are present in the right ulna, right tibia, right patella, and in many phalanges of the right hand. The left femur is fractured both through the uppermost part of the shaft and through the narrowed neck. The calvaria shows a uniform finely mottled appearance (Dr. S. G. Scott).

Calcium and phosphorus metabolism: There was a constant hypercalcaemia (Fig. 6), the serum calcium reaching as high as 10.7 mg. per 100 c.cm. The corresponding figure for the plasma phosphorus was very low—namely, 1.0 mg. per 100 c.cm. The plasma phosphatase was very high: 1.0 mg. (normal 0.15 mg.).

On a known low calcium intake the calcium output in the urine was more than eight times the normal, that in the faeces being approximately normal (Fig. 7).

Operation: Mr. A. J. Walton, Nov. 20th, 1929. A "collar" incision was made in the neck. The left lobe and

FIG. 7.

Effects on calcium metabolism of diet, ammonium chloride, parathyroid extract, and disease of the parathyroid and thyroid.

The calcium excretion was estimated on a known low calcium intake. The horizontal lines represent the calcium intake, which was approximately 100 mg. daily. The urinary calcium excretion is represented by single cross hatching and the faecal calcium excretion by double cross hatching.

isthmus of the thyroid were found to be normal. The left inferior parathyroid gland was replaced by a cystic adenoma which was deeply situated in immediate contact with the inferior pole of the left lobe of the thyroid. It was well encapsulated and was removed intact. A portion of bone was removed from the swelling in the lower end of the right ulna.

Report on specimens removed at operation (S.D. 2806, 1929): Prof. H. M. Turnbull. (1) Left inferior parathyroid body. Macroscopic.—The specimen was pyriform, tense, and fluctuating, and measured 3.7 by 3 cm. (Fig. 8). On section a slightly opaque, blood-stained fluid escaped, and the specimen collapsed. The wall consisted of a thin membrane to the greater part of which was attached a lining of opaque, pale ochreous tissue. This was 0.8 cm. at its thickest, contained cystic cavities and was broken on its mesial aspect into ragged trabeculae.

Microscopic.—The gland is surrounded by a thin capsule of dense collagenous fibrous tissue, and contains numerous large and a few small cysts. These have smooth margins without any reticular or other lining, and are filled with an albuminoid coagulum and occasionally red corpuscles. Between the cysts a mass of mutually compressed cells is traversed by numerous capillaries and a few arteries and veins. Small alveolar spaces are very rare. The cells and their nuclei resemble those of a normal gland. They vary in size, but the mean size is decidedly larger than normal. The cytoplasm is finely granular or vesicular, occasionally coarsely vesicular; a linear cell-membrane usually separates adjacent cells. Groups of cells, particularly near the margins of cysts, are loaded with anisotropic lipid. Glycogen is present in many cells, but is usually scanty and confined to

the periphery. There is no collagen, fibroglia, or reticulum apart from the walls of capillaries and the adventitia of larger vessels.

Remarks.—The appearances indicate a functional hyperactivity rather than an autonomous neoplasm.

(2) *Expanded lower end of right ulna. Macroscopic.*—Slice (1.5 by 1.3 by 0.5 cm.), including both periosteal surfaces. The sawn surfaces were pink and gritty. A hand lens showed closely packed projecting grey spicules in a pink ground. There was no trace of ivory bone.

Microscopic (Fig. 9).—The bone was partially decalcified in Müller's solution. Sections were stained by Kossa's and other methods. Beneath the periosteum on both sides of the bone, passing through the corticalis, completely replacing it in places, and extending throughout the medulla is a cellular collagenous fibrous tissue. The collagen fibres are stained deep red by van Gieson's stain. Spindle fibrocytes are numerous throughout. In the medulla it contains a few small groups of "foam cells." There are many vessels. Most are small, and none is exceptionally wide. Most are sharply defined capillaries, but there are a few veins and arterioles. There are one or two small perivascular hæmorrhages.

The corticalis is for the most part very thin or broken into small isolated trabeculae. The thickest portion is fretted by numerous deep bays of subperiosteal fibrous tissue. It is composed of both coarsely fibred and finely fibrillated (lamellar) bone. The coarsely fibred bone usually forms a core to the lamellar bone; this arrangement is particularly clear in the thickest portion of corticalis. Active apposition is shown by osteoid zones covered by a layer of osteoblasts, and is found upon the greater part of the surface, particularly the outer surface on one side of the bone and the inner surface on the other. The osteoid tissue is almost entirely lamellar. The margins of the calcified bone show numerous Howship's lacunæ, even beneath the osteoid zones. On the inner surface of the corticalis upon one side are numerous large osteoclasts; a few lie upon osteoid tissue, the others occupy lacunæ in bone.

The medulla is beset with small trabeculae of very irregular, deeply notched outline. They are composed of both coarsely fibred and lamellar bone. Coarsely fibred bone predominates, but the bone in process of apposition is almost entirely lamellar. This active apposition is shown by osteoid zones covered by a layer of osteoblasts. Portions of the surface free from active apposition are relatively very rare. They almost always show large osteoclasts in lacunæ. Occasionally groups of several large osteoclasts enclose one or two spicules of bone. Other osteoclasts in the fibrous tissue are not connected with any bone in the section. Most of the osteoclasts are exceptionally large.

The depth of the osteoid zones upon the corticalis and upon the trabeculae in the medulla is obviously very frequently exaggerated by tangential section; tangential section must occur very frequently when the calcified trabeculae are of such very irregular shape. The shape of the osteoblasts varies with the obliquity of the section. Where the zones are cut at right angles to their surface, the osteoblasts are narrow spindles. Drawings were made of many osteoid zones cut strictly at right angles, and were compared with drawings of osteoid zones in the ribs of infants at and shortly after birth, and in callus in the bones of adults from 13 to 22 days after fracture. The osteoid zones in the present case are slightly deeper than the deepest zones in the normal infants, but are no deeper than the zones in the healing fractures.

Remarks.—The fibrous tissue beneath the periosteum and throughout the bone has the uniform and highly differentiated structure of an osteitis fibrosa as opposed to sarcoma. Coarsely fibred bone is not found in the medulla of a normal ulna at any age, and coarsely fibred bone of the kind present in this specimen is not found in the corticalis of an adult. The coarsely fibred bone is abnormal and has been formed during the disease. It is clear, therefore, that the pathological process has caused the resorption of at least a large part of the original corticalis, and almost all the original spongiosa. At the same time, or subsequently, new, coarsely fibred bone has been deposited, and lamellar bone has been laid upon this. At the time of excision of the specimen, both apposition and resorption were in active progress. The fluctuation in these two processes is shown by the presence of osteoid zones upon Howship's lacunæ, and by the occasional presence of an osteoclast upon osteoid zones which everywhere else are covered by osteoblasts. At the time of excision active apposition predominated over active resorption; and, although

past resorption is the most striking feature in the corticalis, it is masked in the medulla by the great number of newly formed trabeculae. The abundance, however, of newly formed bone in this focal swelling of the ulna cannot be taken as characteristic of the changes throughout the skeleton, in view of what was found in Case 3. In Case 3 an even greater formation of new bone was found in focal areas, but in the skeleton as a whole resorption far exceeded apposition.

The bone which had been formed in the excised portion of ulna during the disease is fully calcified, except in the sharply defined osteoid zones. These zones are conspicuously deep, but the measurements described above show that they are not deeper than the osteoid zones formed in the active healing of fractures in healthy adults. There is no histological evidence, therefore, of the cessation of calcification characteristic of osteomalacia and rickets nor of a removal of calcium by chemical solution. The mobilisation of calcium was due to lacunar resorption by osteoclasts. (H.M.T.)

Progress up to three months after operation.—Twenty-four hours after operation Chvostek sign appeared and has persisted since. On the second day pressure upon the bones caused much less pain than previously. The blood chemistry 48 hours after removal of the tumour showed that the serum calcium had dropped to a level below normal—namely, 9.1 mg. per 100 c.cm. (Fig. 6). Simultaneously the plasma inorganic phosphorus rose to 2.8 mg. per 100 c.cm. By the fourth day pressure upon the bones no longer caused pain. The patient has been kept in bed with the left leg fixed in abduction. In controlled radiograms the density of the bone shadows is the same as before operation.

Calcium and phosphorus metabolism.—Latent tetany has persisted in the shape of Chvostek sign, but there has been no manifest tetany, and Trousseau sign has never been present. The calcium and phosphorus levels in the blood are still slightly below normal. The plasma phosphatase is 1.14 mg. The calcium output (Fig. 7), estimated for four three-day periods on the same low calcium diet as before operation, is less than in the normal individual. It corresponds to that of a case of post-operative tetany.

In this case we may say that clinical, radiological, chemical, and histological evidence combine to show that the patient was, by urinary excretion, rapidly losing calcium salts from the skeleton in amounts exceeding eight times the normal.

This gave rise to the complete picture of a disease known to von Recklinghausen 40 years ago, in days when it was impossible to solve the problem of its aetiology. His insistence that the disease was not osteomalacia is borne out by all the additional facts brought to light by our new methods. Unfortunately, the literature of the subject shows only too plainly that his work has been largely overlooked, for we find hyper-parathyroidism being confused with osteomalacia in 1929.

Clinical Characteristics of Hyper-parathyroidism.

Of the 14 cases published to date, in nine a parathyroid tumour was removed, in two one or more histologically normal parathyroid bodies were removed,^{70 73} and in three there was no operation on the neck.^{74 75} The condition is reported twice as frequently in women as in men, the commonest ages being 30 and 55. The histological picture of osteitis fibrosa was established in seven cases, and in two of these giant-celled tumours are mentioned. Pain in the bones and spontaneous fractures were common. Polyuria occurred in three cases, and in one of these bilateral renal calculi were found.⁷⁶ Hypotonicity of muscles is described in two cases. In nine cases there was no palpable swelling in the neck, but on exploration only two of these failed to show a parathyroid tumour. In these two cases it may be that a tumour was present and was not found. In those cases where radiograms are mentioned there was greatly diminished density of the bone shadows. Sometimes there was radiological evidence of cysts, but these only rarely expanded the corticalis. The serum calcium figures varied between 13.1 and 23.6 mg. per 100 c.cm., the plasma phosphorus between 1.0 and

2.7 mg. The output of calcium in the urine varied from a slight increase to eight times the normal figure.

The tumours removed were usually encapsulated adenomata, often cystic, and measuring about 2.5 cm. in diameter. The largest tumour removed was 5 by 3.5 by 3 cm. and has been described as a malignant adenoma.^{77 78} In the majority of cases pain in the bones was abolished immediately after operation, and the mechanism of this is difficult to conceive. In one case⁷⁹ removal of the tumour promptly abolished polydipsia and polyuria. In many cases the levels of the blood calcium and phosphorus and the excretion of calcium in the urine were restored to normal. Sometimes there was temporary hypocalcaemia and even oliguria, with subnormal excretion of calcium in the urine.⁸⁰ Latent tetany after operation was common, and manifest tetany often occurred, with marked variations in severity. It was fatal in one case only—namely, that of Beck,⁸¹ where two parathyroid tumours were removed. This is the only case of hyper-parathyroidism recorded in which more than one tumour was found. In Snapper's case⁸² tremor and acute mania occurred three weeks after operation, at a time when the serum calcium had dropped to 8.6 mg. per 100 c.cm. The condition was completely relieved in three days by the use of parathormone injections in conjunction with a preparation of calcium given intravenously.

With regard to the later effects of operation it is too early to make a statement. There is no doubt that symptomatic improvement occurs after extirpation of a tumour; eight of the nine patients surviving operation all showed this, and it was possible for some of them to dispense with sticks and crutches. In the two cases where normal parathyroid glands were removed, the hypercalcaemia persisted and little improvement occurred. Considering the generalised and extensive destruction of bone, one would expect complete repair to take many months or years. It is a very different question from osteomalacia or rickets, where osteoid tissue merely awaits conversion into bone by a process of calcium deposition. Some authors claim that an increase in density in the radiographic shadows of bones was to be seen in their cases a few months after operation. It is of great interest that three years after operation no such change could be demonstrated in Mandl's case.

Pathogenesis of Generalised Osteitis Fibrosa (Hyper-parathyroidism).

In view of all these cases there can be little doubt that the essential change in generalised osteitis fibrosa is a removal of calcium from the skeleton owing to parathyroid hyperactivity, the condition being similar to the experimental administration of parathormone to animals. In referring to the skeletal changes the term osteomalacia is frequently used, but there is no histological evidence of true osteomalacia. The calcium is removed by lacunar resorption by osteoclasts. The resorption is widespread, but it is accompanied by focal formation of new bone. In the formation of new bone the osteoid zones are frequently deeper than in the normal bones of adults, but as was shown by Schmorl⁸³ and independently by Turnbull in the two cases described here for the first time, the unusual depth is merely evidence of rapidity of formation, the greatest depths being no greater than in the healing of fractures in healthy adults.

FOCAL OSTEITIS FIBROSA.

Of much more common occurrence than the generalised disease is focal osteitis fibrosa. This is a condition affecting one or more bones, usually not disabling, of slow progress, and showing a tendency to become arrested. It occurs chiefly in adolescence and is often symptomless until spontaneous fracture occurs.

In those cases which I have investigated, the

serum calcium and plasma phosphorus and phosphatase have been normal. (Table I).

I shall now relate a case in which the calcium balance was normal, a finding in striking contrast to that of the generalised disease.

CASE 5. *Osteitis fibrosa in multiple foci.*—A married woman of 27 years (L. H. Reg. No. 40007, 1930).

Clinical history.—Twelve months: enlargement of right arm above elbow. Three weeks: aching pain in arm began in fourth month of pregnancy. No fracture nor history of fracture. Two children well.

Calvaria normal. Sclerotics white. Slit-lamp examination showed within the foetal nucleus of each lens crowds of tiny white glistening dots surrounded by a small area of cloudy lens. No visual defect. No tumour felt in neck. Diffuse irregular enlargement of right humerus with outward bowing in upper part. No deformity of other bones. Wassermann reaction negative. Radiograms of bones: right humerus and radius show pale trabeculated areas with expansion of bone. Similar, less definite areas round acastabulum and in left ischium. Controlled radiograms showed that outside these areas the shadows of all bones were of normal density. The blood chemistry was found repeatedly to be normal (serum Ca 9.8 mg. per 100 c.c.m., plasma phosphorus 3.0 mg., plasma phosphatase 0.363 mg.). On a known low calcium intake the calcium output in urine and faeces was normal (Fig. 7).

This is not an isolated instance of a normal calcium balance in focal osteitis fibrosa; I found it also in the first case shown in Table I.

Taken in conjunction with the above observations on the blood of seven other cases, the finding of a normal calcium metabolism is of far-reaching importance. Supported as it is by the normal density of the radiographic shadows of bones, it is evidence strongly against hyper-parathyroidism. It is of vital importance in such cases to realise that, although many bones are affected, the condition is totally different from the generalised disease and that exploration of the neck is clearly unjustifiable.

I shall now go on to discuss the effects of the thyroid hormone and of thyroid disease on the metabolism of calcium and phosphorus.

EFFECTS ON CALCIUM METABOLISM OF THYROXIN AND THYROID DISEASE.

It is, of course, known that the internal secretion of the thyroid gland raises the basal rate of combustion of carbohydrate, fat and possibly protein, consequently appreciably increasing the total heat production of the organism. Its effect, however, on inorganic salt metabolism had until about two years ago largely been ignored. Parhon,⁸⁴ in 1912, showed a marked loss of calcium in rabbits fed with lethal doses of thyroxine, and her work definitely suggests a stimulating effect of the thyroid on calcium metabolism. Kummer,⁸⁵ in 1917, studied for 13 days the metabolism of a man aged 42 suffering from exophthalmic goitre. Two and a half litres of milk were given daily, which meant that the calcium intake was approximately 5 g. per day. No determinations were made of the basal metabolic rate, and control figures for calcium were taken from the literature. Because the quantity of calcium in the urine was normal, and that in the faeces was large, he attributed the high faecal calcium to a difficulty in absorption rather than to abnormal excretion. He concluded that the mineral excretion was high but very irregular, both the calcium and phosphorus losses being especially great.

It is to Aub, Bauer, Heath, and Ropes,⁸⁸ however, that we owe an accurate knowledge of the part played by the thyroid in calcium metabolism. Working with low calcium diets they have found that hyperthyroidism is associated with a markedly increased calcium excretion, and that the mechanism by which this is brought about differs widely from that of the parathyroid. They made observations on 18 cases of thyroid disease, and on two normal individuals given thyroid, and in all these cases they found consistent results. In eight cases of exophthalmic goitre the elimination of calcium was 231 per cent. above the average excretion per kilo found in control cases. In one severe case of exophthalmic goitre the calcium excretion was eight times the normal. These increases were out of all proportion to the effect on the basal metabolic rate, the average increase of which was only 55 per cent. above normal. During treatment with iodine, and after subtotal thyroidectomy, as the patient improved and the basal metabolic rate approached the normal, the calcium excretion also returned towards normal.

Additional evidence was furnished by two cases of so-called hyper-functioning adenoma of the thyroid.

reached its height only when the basal metabolism was falling, and this increase was maintained long after the effect on the basal metabolism had subsided. This calcium stimulation, therefore, had a longer latent period and more prolonged effect than any other function of the thyroid yet described.

The effect of thyroid on the blood in this case is quite astonishing, when we recall that the serum calcium values in thyroid disease are normal. In exophthalmic goitre, even though calcium excretion may be eight times the normal, this high rate of elimination is not obvious in the blood, for there is no hypercalcaemia. And yet thyroid treatment has been found to raise the serum calcium in parathyroid tetany!

Action of Thyroid and Parathyroid Contrasted.

As to further contrasts between the thyroid and parathyroid mechanism we notice from Aub's figures⁸⁸ in Fig. 7 that, of all the conditions he studied, it was in hyperthyroidism alone that he found a distinct increase in faecal as well as in urinary calcium excretion. It was also obvious that the faecal calcium was not unabsorbed calcium, for there was more present

GENERALISED OSTEITIS FIBROSA: HYPER-PARATHYROIDISM.

Descriptions of Illustrations on Coloured Plate.

FIG. 4. (Case 3).—Bones ($\frac{1}{4}$ -scale) in a case of generalised osteitis fibrosa with parathyroid adenoma.

(A) *Left femur.*—Note fractures through cysts in centre of shaft, area of red-brown tissue in inner condyle, and coarse grey trabeculae of bone bordered by fibrous tissue in spongiosa of neck.

(B) *Sixth right rib.*—Note nodule of red tissue containing small cysts and expanding bone.

(C) *Third right rib.*—Note tumour expanding bone.

FIG. 5. (Case 4).—Controlled radiogram of right forearm in a case of hyper-parathyroidism. The density of the X-ray shadows of the bones is contrasted with that of a control subject of the same age, sex and build exposed simultaneously on the same negative. Note the diminished density of the

bone shadows and the pale cyst-like areas, some of them trabeculated. The control is marked E.

FIG. 8.—Tumour (actual size) of left inferior parathyroid body removed at operation in Case 4. In the cut section note the relatively large amount of solid tissue. This is functionally hyperactive parathyroid tissue.

FIG. 9.—Histological section of portion of expanded lower end of right alna removed at operation in Case 4. (Müller's solution; Weigert's iron haematoxylin and van Gieson's mixture.) There is fibrous tissue beneath the periosteum and throughout the bone. A large part of the original corticall has been removed by osteoclastic lacunar resorption. The bone formed during the disease is fully calcified except in the osteoid zones. These are not deeper than those formed in the active healing of fractures in healthy adults.

The calcium excretion was raised to almost twice the normal and fell definitely after the adenomata were removed. The effect of the administration of thyroid was studied in two normal individuals. In one of these gr. 42 of thyroid extract were given by mouth over a period of four days, and on the fourth day 10 mg. thyroxin were given intravenously. Ten days later apprehension, fever, malaise, and tachycardia appeared. At this point the basal metabolic rate had risen to plus 48 per cent., and the calcium excretion was doubled.

These studies clearly show that the thyroid hormone stimulates calcium excretion to an extent far in excess of that produced by acids or even by parathormone.

But if thyroxin increases calcium excretion, then myxoedema may be expected to be associated with a diminished calcium output. This was clearly established by these authors in six cases, where they found the average excretion to be 40 per cent. below the normal. Administration of thyroid to these patients with myxoedema resulted in an increase both in metabolism and in calcium excretion.

Thyroid Treatment of Parathyroid Tetany.

Striking effects were obtained by the use of thyroid preparations in a case of post-operative tetany.⁸⁸ Sufficient thyroid extract by mouth and thyroxin intravenously were given to raise the basal metabolic rate from minus 14 to plus 22 per cent. This occurred over a period of two weeks, during which time the blood calcium rose from 6.7 to 11.9 mg. per 100 c.cm. The calcium excretion increased to three-fold its previous value. This increase of calcium in the blood and excreta was still present six weeks after the last dose of thyroid extract, a surprising result which was confirmed later in the same patient. This effect on calcium is not an indirect result of the raised metabolic rate, for the increased calcium excretion

in the faeces than was present in the food. Why the faecal excretion should be increased above this basal level only by the thyroid is very difficult to understand, particularly as the blood calcium in thyroid disease is normal.

In hyperthyroidism a marked increase in phosphorus excretion was also found.⁸⁶ This increase was quantitatively such as to suggest that most of the calcium excreted came from tertiary calcium phosphate in bone.

Is the high calcium excretion of hyperthyroidism dependent on the increased thyroid secretion, or is it merely an accompaniment of an increased metabolism? This question was answered⁸⁶ by determining the calcium excretion in cases with a high metabolism due to prolonged fever and leukæmia. Three out of four such cases showed a normal calcium excretion in spite of an elevation of general metabolism, varying from plus 21 to plus 41 per cent. We may therefore conclude that an increased calcium excretion is not necessarily a function of a raised metabolic rate alone.

Does thyroxin exert a stimulating effect on the parathyroid glands? The normal blood calcium in hyperthyroidism and after intravenous thyroxin argues against this. But very little is known about the threshold of calcium excretion, and we have pointed out elsewhere²² that the administration of parathormone may sometimes cause a great increase of calcium excretion without appreciably raising the serum calcium level.

We recently attempted²² to solve this problem by animal experiments in which the action of thyroxin was investigated after total thyro-parathyroidectomy. In other words, we wanted to know whether thyroxin would increase the calcium output in animals deprived of their parathyroids. We worked with dogs and cats kept in metabolism cages on a low calcium diet. After operation they were allowed to go into tetany, and

GENERALISED OSTEITIS FIBROSA: HYPER-PARATHYROIDISM.

OSTEOPOROSIS IN EXOPHTHALMIC GOITRE.

FIG. 12.

FIG. 11.

FIG. 13.

then the smallest dose of parathormone required to keep each animal just free from tetany was determined. Subsequently large doses of thyroxin were injected every second day, and the dose of parathormone was kept constant. In the case of the cats the experiment was a complete failure; thyroxin made them ill and they died in tetany. The dogs were more satisfactory, but a gradual drop in the serum calcium with the appearance of tetany ten days after the last dose of thyroxin made us decide that the conditions of the experiment were too exacting upon the available stores of calcium. We intend to repeat the experiment with intervals of high calcium therapy, during which, of course, we shall lose our observations on calcium balance.

The alternative explanation—namely, that the thyroid exerts a direct effect on bone katabolism—is not an unlikely one, especially as this would be in agreement with the general action of thyroid on other body tissues.

Radiographic Studies of Bones in Exophthalmic Goitre.

The studies of Kummer⁸⁸ on the metabolism in exophthalmic goitre led him to the conclusion that the calcium excretion was high in this disease. He was

phorus are consistently normal in hyperthyroidism. The phosphatase values in the plasma are often high, though the increase is neither so great nor so con-

TABLE II.

sistently present as in the case of osteitis deformans. There seems to be no relation between the duration of the disease, the degree of osteoporosis, and the values for the plasma phosphatase (Table II.).

OSTEOPOROSIS IN EXOPHTHALMIC GOITRE.

In view of the chemical and radiographic studies just described it became a matter of importance to

OSTEOPOROSIS IN EXOPHTHALMIC GOITRE.

Descriptions of Illustrations on Coloured Plate.

FIG. 11. (Case 6).—Right femur (actual size) in a case of exophthalmic goitre. The perfectly homogeneous ivory-like corticalls is seen in the normal bone is here interrupted by many pink longitudinal narrow streaks and rows of dots.

FIG. 12.—On the left is seen a macerated specimen of the left femur in Case 6. It has been sawn longitudinally and digested in pancreatic solution. Note the pitting of the corticalls and the conversion of the spongiosa into an

exquisitely delicate lace of fine bony threads. On the right is a control specimen of the left femur from a healthy subject of the same age and sex, prepared in the same way.

FIG. 13.—Histological section of corticalls of centre of right femur in Case 6. (Güller's solution; Delafield's haematoxylin and eosin.) Subperiosteal area. Note general osteoporosis, lacunar resorption by osteoclasts, an osteoid zone, and perforating canals.

apparently the first to make the exceedingly interesting observation that "as judged from radiograms this calcareous demineralisation affects the bony system." In 1927 Bernhard,⁸⁷ investigating a case of exophthalmic goitre in a woman of 47, described radiograms showing poverty of calcium in the bones.

Aub and his co-workers⁸⁸ observed independently the same phenomenon. They took controlled radiograms of the hands of a patient with exophthalmic goitre of 17 years' duration and demonstrated marked poverty of calcium in the bones.

In their paper they point out that the change is unlikely to be a constant finding in hyperthyroidism, since adequate calcification of the bones should be possible in cases where the diet contains sufficient calcium.

Plummer and Dunlap⁸⁹ found radiographic evidence of severe osteoporosis in three cases of hyperthyroidism, in two of which carcinomatosis of the bones had been suspected. An autopsy on one of these cases revealed generalised osteoporosis, especially of the calvaria and ribs, the latter showing multiple fractures. No histology is recorded. These authors state their belief that the process of decalcification of bone in hyperthyroidism is usual.

In our experience controlled radiograms of the bones in exophthalmic goitre reveal poverty of calcium in less than half the cases examined (Fig. 10). In two cases of hyperthyroidism with spontaneous fracture we have found radiographic evidence of decalcification not only of the fractured bone but also of all other bones examined.

Chemistry of the Blood in Exophthalmic Goitre.

The demineralisation of bone seen in radiograms is, in fact, a widespread osteoporosis brought about by osteoclastic lacunar resorption. Before demonstrating this it will be of interest to inquire into the values found for the plasma phosphatase in cases of exophthalmic goitre. It has already been emphasised that the serum calcium and plasma inorganic phos-

phorus are consistently normal in hyperthyroidism. Cases 6 and 7 serve to show that severe generalised osteoporosis may be found in hyperthyroidism of many years' duration.

A search of the literature revealed the fact that this condition was known to von Recklinghausen and Askanazy, though they had no means of determining the true relation between the thyroid disease and the osteoporosis.

Case 12 of von Recklinghausen.⁹¹ (See also Koeppen.⁹²) Juvenile osteomalacia with Basedow's disease.—A single woman of 23, dressmaker in Strassburg. There had been no puerperium. Five years' history of goitre, prominence of eyes, and palpitation. Two years before: pain in back brought to her notice that her spine was twisted. Later, pain in both arms, sometimes cramps in hands and feet. On examination: exophthalmos, tremor, tachycardia, enlarged heart. Slight kypho-scoliosis. Trousseau sign absent.

Necropsy: great enlargement of thyroid and thymus. Hypertrophy of heart. Several of the bones are marked by uncommon redness for that age, especially the cortices of the long bones, which are everywhere marked longitudinally with vascular striae. In the calvaria, scapula, and iliac bone there are definite vascular striae. All the bones saw like rotten wood, the sternum and calvaria being readily cut with a knife. Maceration revealed numerous small exostoses corresponding to the insertions of tendons. Histologically, resorption spaces were abundant in the corticalls, and they often contained whole nests of osteoclasts.

A comment is made that the degree of osteoclastic resorption was equalled only by that found in Case 7 (generalised osteitis fibrosa). Both authors describing this case believed that the bone changes were secondary to the exophthalmic goitre, but they expressed a doubt as to whether this form of "osteomalacia" was identical with the ordinary puerperal form.

Askanazy's case with thyroid tumour.⁹³ Calcium metastases and progressive atrophy of bone.—A woman, aged 61. History of goitre for five years, no pressure symptoms. Thirteen months before, she had been in bed with sacral backache following a fall. Three weeks before: renal colic, passed two calculi. Died of suppurative pyelonephritis.

At necropsy: large retrosternal goitre which had become carcinomatous and had given rise to metastases in the lungs. Multiple calcified areas in lungs, one in gastric mucosa. Purulent pyelitis with renal calculi; perinephric abscess.

"On palpation of the ribs at their angles a few small exostoses were felt. The spongiosa of the ribs was wide-meshed. In the spongiosa of the vertebrae also there were spaces up to the size of lentils. The bony spicules could be pressed in more easily than usual. In the macerated vertebrae the spicules, both in the bodies and in the laminae, were like bony threads."

Sections were made from spine and sternum. The histological picture revealed resorption of bone of greater

FIG. 10.

Controlled radiogram of hand showing osteoporosis in exophthalmic goitre. (From the first case in Table II.)

The density of the X ray shadows of the bones is contrasted with that of a control subject of the same age, sex and build exposed simultaneously on the same negative. The diminution in density of the bone shadows is uniform. There are no pale cyst-like areas.

severity and extent than could have been predicted from the macroscopic appearance of the bones. "The picture in every section examined was striking and beautiful. One has rarely observed in so dramatic and extensive a way the pure uncomplicated process of progressive bone resorption by osteoclasts. Innumerable typical osteoclasts lay in lacunae in the bone, and lacunar resorption was universal. In many fields I could count 40 to 80 osteoclasts lying in an uninterrupted row." Occasionally apposition of new bone in narrow layers was observed, but by no method of fixation or staining could osteoid tissue be demonstrated.

CASE 6. *Osteoporosis in exophthalmic goitre.*—A girl of 19 years (L. H. Reg. No. 23035, 1928).

Clinical history.—Patient was a factory hand. For five years she had noticed breathlessness, palpitation, loss of weight, and prominence of the eyes. For 10 months there had been gradual enlargement of the neck, and she became unable to work. Weight, 106 lb. 5 oz. Height 5 ft. 7½ in. Fine tremor, exophthalmos, and great enlargement of the thyroid. Pulse 120, regular. Heart hypertrophied, with a thrusting apical impulse displaced 1 in. to the left. Treatment with iodine reduced the pulse-rate to 100. At operation the isthmus and right lobe of the thyroid were removed. Death occurred 21 hours later.

Summary of necropsy (P.M. 469/1928). Prof. H. M. Turnbull. Broncho-pneumonia. Operation: removal of isthmus and right lobe of thyroid. Graves's disease. Cellular hyperplasia and focal lymphocytic infiltration of thyroid gland. Hypertrophy of thymus (47.5 g.). Moderate exophthalmos. Exceptionally abundant lymphadenoid tissue throughout body. Hypertrophy of myocardium. Focal areas of necrosis and fibrosis in right papillary muscle of mitralis. Large area of organised pericarditis upon right ventricle. Fatty degeneration, microscopic central focal necroses, and considerable portal fibrosis of liver. Slight fatty degeneration of kidneys. Osteoporosis.

Bones. A. *Macroscopic examination.*—The right femur, right humerus, left radius, and left ulna were sawn in longitudinal section. In no bone was the corticalis appreciably thinner than normally; that of the femur was 0.7 cm.

thick. But the perfectly homogeneous ivory-like cut surface which is seen in the normal bone was interrupted by many pink longitudinal narrow streaks and rows of dots. These were especially numerous in the femur (Fig. 11).

B. *Macerated specimen* (Fig. 12).—The left femur, sawn longitudinally and macerated, was compared with a similarly prepared left femur from a healthy subject of the same age and sex. The femur measures 46.5 cm., is 0.1 cm. longer than this control and is greater in every external measurement; otherwise there is no difference in gross and fine structure externally. In spite of its greater size it is astonishingly light in comparison with the control (dry weight 206 g., control 291 g.). Internally the corticalis is thicker than in the control at the junction of the neck with the internal surface of the shaft. It is considerably thinner in the middle third of the shaft, and much thinner in the lower third. The thick area in the neck is so pitted as to be almost spongy in texture. In the upper two thirds there is a row of pits forming a vertical groove close beneath the surface, and internal to this are many scattered pits. In the lower third alone does the corticalis show the ivory-like surface of the control. The medullary cavity is greatly enlarged, 12 cm. of the upper half of the shaft being entirely free from trabeculae in comparison with 3 cm. just above the centre in the control. The architecture of the spongiosa is not altered, but the trabeculae are much more slender throughout and, except in the anatomical neck and condyles, form an exquisitely delicate lace.

C. *Microscopic examination.*—A longitudinal slice of the corticalis from the centre of the femur was fixed in 4 per cent. saline formaldehyde and transferred to Müller's solution. It was later split; one half was treated with Müller's solution alone, in the other half decalcification was hastened by a drop of nitric acid. Both pieces were cut, and sections were stained by Kossa's and other methods.

The corticalis of a large long bone in a normal subject of ten years or over consists of a compact mosaic of lamellar systems traversed by vessels. Most of these vessels run in the long axis of the bone in Haversian canals surrounded by Haversian lamellar systems. Uniting these are a few transverse or oblique vessels, either in Haversian canals or in perforating canals. Haversian spaces are very rarely met.

In the present case the corticalis consists of a substantial reticularis (Fig. 13), instead of a substantia compacta. A net of trabeculae of lamellar systems encloses medullary spaces, of which the longitudinal axis is the greatest. The general arrangement of the spaces corresponds to that of the vessels in a normal bone. Almost all the Haversian canals and systems have disappeared; there are several perforating canals (Fig. 13). The trabeculae immediately beneath the periosteum is narrow, and it shows several large and small subperiosteal bays filled with a vascularised, delicate fibrous tissue. The largest medullary spaces lie immediately beneath this and traverses the whole 1.8 cm. of the section. The medullary spaces contain hamatogenous marrow. The boundaries of many of the spaces show very numerous Howship's lacunae, many of which are occupied by osteoclasts (Fig. 13). Very few of the trabeculae show an osteoid zone (Fig. 13); the depth of such zones is within the limits measured in the ribs of newly born infants. The trabeculae are otherwise fully calcified.

Remarks.—The compact tissue of the corticalis has been greatly rarefied by osteoclastic lacunar resorption; there is no histological evidence of a cessation of calcification such as is found in rickets and osteomalacia nor of a removal of calcium by chemical solution. The macerated specimen shows that this resorption is not confined to the corticalis, but is apparently greater throughout the spongiosa and medullary cavity. (H. M. T.)

This is not an isolated instance of osteoporosis occurring in exophthalmic goitre; we have observed it in other cases, of which the following is an example.

CASE 7.—*Osteoporosis in exophthalmic goitre.*—A single woman of 28 years (L. H. Reg. No. 24678, 1929). History of five years' swelling of neck, nervousness, loss of weight, palpitation. Weight 75 lb. 19 oz. Height 5 ft. 3 in. Enlarged thyroid, marked exophthalmos, fine tremor. Pulse 120, regular, fell to 80 on treatment with iodine. Died five hours after partial thyroidectomy.

Osteoporosis is so severe that the spongy bone in the lower end of the femur exists only in patches. The trabeculae composing this spongiosa are fine bony threads readily crushed on slight pressure. The corticalis is only slightly affected. The femur is 44.4 cm. long and, after maceration, its dry weight is 226 g. The femur of a healthy woman, aged 22 years, was similarly prepared. Its weight is 378 g. and its length 46.0 cm.

Neither atrophy from disuse nor senile osteoporosis can enter into these observations, for these patients had been up and about until a few weeks before death, and were essentially youthful.

Hyperthyroidism differs from hyper-parathyroidism in that there is no increase of calcium in the blood. But calcium is removed from the skeleton in both, and in both the mechanism of removal is a lacunar resorption by osteoclasts.

BRITISH HUMANE ASSOCIATION.—Last year this association gave free light and electrical treatment to 128,000 persons. A supplementary clinic is to be opened for the benefit of those who can pay the ordinary fee. The institution, which controls the London Light and Electric Clinic, was founded and endowed by the late Mr. Campbell-Johnston, but the death duties have made such serious inroads upon the endowment fund that the development schemes prepared by the founder must remain in abeyance unless more money is forthcoming. At the annual meeting of the Association held recently Lord Scarbrough, Sub-Prior of the Order of St. John of Jerusalem, explained that upon the founder's death last year its control passed to the Order.

END-RESULTS OF MANIPULATION OF THE BACK.

BY E. W. RICHES, M.C., M.S. LOND., F.R.C.S. ENG.,
ASSISTANT SURGEON TO THE MIDDLESEX HOSPITAL AND
TO THE HOSPITAL OF ST. JOHN AND ST. ELIZABETH.

A CONSIDERABLE number of the patients who attend a general hospital complaining of pain in the back are sent to the orthopaedic department, often after previous investigation by a urologist or gynecologist. In the Orthopaedic Department at Middlesex Hospital, under Mr. Blundell Bankart, many of these cases are treated by manipulation of the back. At the end of 18 months as registrar in this department I have tried to obtain some statistical record of the results of this form of treatment. Although various writers have recorded the results of their operative or other treatment of these disabilities, there appears to be no similar record of the results of manipulation. The object of the present inquiry has been to ascertain the final results of manipulation of the back, and to show its possibilities and limitations in the different conditions which give rise to what American writers have termed "low back pain."

Material Available.

The records of the clinic have been examined from 1921 to October, 1929. During this period 113 patients have undergone manipulation of the back; ten were so treated in the years 1921-25, and 103 from 1925 to October, 1929. Most of the patients have been re-examined, and to all of them a questionnaire has been sent. Replies were received from 78 (69 per cent.); one patient had died from other disease, and in two cases the information obtained was inadequate. There remain 75 cases on which these statistics are based, the earliest having been treated in 1921, the latest in October, 1929.

Every patient was asked whether, as the result of manipulation, the condition of the back was cured, improved, unchanged, or worse. Other questions related to duration of after-treatment, length of time off work, both before and after manipulation, and whether there had been any return of pain. It is realised that the answers to such questions vary with the type of patient, and in particular that the term "improved" requires further definition. Such an answer has therefore not been accepted unless the patient has returned to full work and is not getting any more than occasional pain after over-exertion. In this way several patients who expressed themselves as "improved" have been classified finally as "unchanged."

TABLE I.—Total Cases Manipulated.

Condition.	No.	Sex.		Average age.	Improved	Not improved

6 Neuritic spine	4	0	4	43.3	0 (0)	4 (100)
Total ..	75	28	47	37.5	56 (74.7)	19 (25.3)

Manipulation was carried out in every case under an anæsthetic; as a rule nitrous oxide and ether was used, although in a few cases gas alone was given; the better relaxation given by ether is generally desirable. The manipulation consists essentially of forcible flexion of the spine, a rotatory movement of the pelvis first to one side and then to the other (the "osteopath's twist"), and finally forcible hyper-

extension of the whole spinal column. In some cases lateral flexion is added. The purpose of the procedure is to restore the normal range of spinal movements. The patient gets up on the day after manipulation, starts massage and exercises on the second day, and is discharged on the third day. The after-treatment is designed to maintain the mobilisation produced by manipulation, and massage is gradually replaced by exercises which the patient can carry out at home. Table I. shows the total number of cases manipulated, classified in their several groups; those cured or improved are tabulated under the heading "improved," whilst those unchanged or worse are called "not improved."

Influence of Trauma.

In the cases labelled "strain" (Groups 1, 2, and 3) it was possible to obtain a definite history of injury in 38—i.e., 65.5 per cent.; some gave a history of sudden onset without trauma, in some the pain followed operations or childbirth, and in the remainder the cause was probably postural. It is noteworthy that the results of manipulative treatment were better in cases which were definitely traumatic in origin, as shown in Table II.; moreover, the replies from these patients were more enthusiastic.

TABLE II.—Total Cases giving a Definite History of Trauma (38).

A—Improved	{ "Cured" 15 } 37 (97.4) %
	{ "Improved" 22 }
B—Not improved	{ "Unchanged" 1 } 1 (2.6) %
	{ "Worse" 0 }

The one traumatic case not improved was a chronic back strain which was manipulated in July, 1928; the woman did not return for further treatment, but resumed work after three weeks.

The nature of the exciting injury has been ascertained in these 38 cases, and is shown in Table III.

TABLE III.

	Fall.	Lift- ing.	Stoop- ing.	Blow.	Foot- ball.	Misc.	Total.
Chronic back strain	6	7	3	4	1	2	23
Sacro-iliac strain	8	3	—	1	1	—	14
Lumbo-sacral strain	1	—	—	—	—	—	1
							38

In most cases the injury was produced by a sudden unguarded movement; in some it was due to lifting or carrying an unusually heavy weight, and in a few it was occupational.

Value of X Rays.

X rays were taken in the majority of the cases; this is now done as a routine, but in the strain groups it is a negative X ray which confirms the diagnosis. Apart from showing gross arthritis when present, X rays have revealed the existence of anatomical anomalies such as sacralisation of the last lumbar vertebra, articular tropism or spina bifida, but in no case has this appeared to affect the diagnosis. Calcified glands have also been shown in some cases and fracture of a lumbar transverse process in one; this patient had sacro-iliac strain on the same side which was successfully treated by manipulation, the fractured process producing no symptoms.

TABLE IV.—Chronic Back Strain.

Total cases—30. (M. 15, F. 15.)			Traumatic cases 23		
A—Improved	{ "Cured" 13 }	26 =	10 }	22 =	
	{ "Improved" 13 }	86.7 %	12 }	95.2 %	
B—Not improved	{ "Unchanged" 4 }	4 =	1 }	1 =	
	{ "Worse" 0 }	13.3 %	0 }	4.3 %	

Of the four cases classed as "not improved" in Table IV. three have not returned for further treatment. One has been seen recently and now states that she is improving with continued massage and exercises. The term "chronic back strain" is used to denote a lesion in some part of a comparatively wide area, but in most cases it is applied to a strain

of the erector spinæ or the ligaments deep to it. The typical history is of a stabbing pain following a sudden movement made in falling or lifting. On examination there is a tender spot over some part of the erector spinæ; the affected muscle is in spasm, and lateral flexion away from that side is painful and limited; X ray is negative. The underlying pathology is probably the tearing of a few muscular or ligamentous fibres, producing a little hæmorrhage and followed by the formation of fibrous tissue which causes pain when it is stretched. Manipulation aims at putting the joints of the spinal column through a full range of movements and breaking down any fibrous adhesions.

A male, aged 39, a general worker in a cemetery, five years previously, whilst digging, felt as if something had snapped in his back. Since then he had had pain in the left side of the back, aching and gripping in character, and he had been unable to work for a year. On examination there was tenderness over the left erector spinæ with spasm and limitation of movement. The back was manipulated in April, 1927; he had massage and exercises for a month and returned to work in two months. Two and a half years later he reported that there had been no return of pain.

It was necessary to repeat the manipulation in four cases in this group and in one a spinal support was given.

TABLE V.—Sacro-iliac Strain.

Total cases—25. (M. 4, F. 21.)				Traumatic cases 14	
A—Improved	{ "Cured "	5	23 =	5	14 =
	{ "Improved "	18	92.0 %	9	100 %
B—Not improved	{ "Unchanged "	2	2 =	0	0
	{ "Worse "	0	8.0 %	0	

Both the cases not improved in Table V. have had arthrodesis of the affected joint (Smith-Petersen operation); in one the pain was relieved on the operated side but recurred on the other side 18 months later, and she is now awaiting arthrodesis of that side. The other was operated on only six weeks ago, and her condition is so far satisfactory. Sacro-iliac strain is regarded as a genuine condition giving a constant characteristic clinical picture. There is usually a history of a sudden unguarded movement, as in a fall, which produces pain localised to one or other sacro-iliac joint; subsequently there is a peculiar sense of insecurity. On examination the most important sign is tenderness localised to the posterior superior iliac spine and just below it; this is elicited by observing the patient wince on deep palpation in this spot and not by asking "does that hurt?" Another constant sign is pain referred to the joint on raising the leg with the knee extended; pain on compression or separation of the iliac crests is sometimes present. There is no sign of gross disease and X ray is negative. The pathological condition is assumed to be due to a strain of the whole sacro-iliac joint; the normal range of movement in this joint is small, and a slight excess of movement produces strain. Tuberculous disease here is not common, and the patient rarely comes before an abscess has formed or positive X ray signs are present. In some cases there may be arthritis of the joint associated with a general spinal arthritis. In manipulation the twisting movement is the most important, and is usually productive of cracking sounds assumed to be due to the tearing of adhesions.

A female, aged 26, a shop assistant, complained of pain in the lower part of the right side of the back for three months; it had come on after carrying a heavy suit case and was worse on going upstairs. On examination there was tenderness localised to the right posterior superior spine on direct pressure, and pain here on flexion of the right thigh with the knee extended. The back was manipulated in November, 1925, and she returned to work in a week; four years later she reported that the treatment had been very successful and that there had been no return of pain.

Statistically, this is the most satisfactory group, but the percentage of complete cures is not so high as in the chronic back strains. It was also necessary to manipulate twice in five cases and three times in four. Cases which do not respond to manipulation can be cured by immobilisation by arthrodesis.

Table VI. does not represent the proportion of cases of lumbosacral strain attending the clinic; they are not usually manipulated, as it has been found

TABLE VI.—Lumbo-sacral Strain.

Total cases—3. (M. 1, F. 2.)			Traumatic cases 1.		
A—Improved	“Cured”	0 1 = 33.3%	0 1 =	1 100%	
	“Improved”	1 33.3%			
B—Not improved	“Unchanged”	2 2 = 66.7%	0	0	
	“Worse”	0 0 = 0%			

elsewhere that they are not as a rule permanently improved by manipulation. The characteristic clinical feature is tenderness localised accurately to the lumbosacral junction in the mid-line and just to either side of it. There is usually pain on hyperextension, whilst flexion is free, being carried out at the intervertebral joints above the lumbosacral junction.

A male, aged 16, an apprentice fitter, had fallen on to his back in the gymnasium two years previously and had since complained of increasing pain over the sacrum. On examination there was tenderness in the mid-line at the lumbosacral junction; flexion was free, but hyperextension and lateral flexion were resisted. There was some spasm of each erector spinae but no deformity of the spine. The back was manipulated on Dec. 6th, 1927, and he had massage and exercises for three months, after which time he was quite well. Pain returned in February, 1929, and was relieved by exercises in one month. It recurred in September, 1929, and was relieved by a further two months' course of exercises.

The recurrence of pain in lumbosacral strain after manipulation is also illustrated by one of the cases already included as sacro-iliac strain.

She strained her back whilst shaking a mat, and when examined had a typical left sacro-iliac strain. During the time she was waiting to come in for manipulation she fell downstairs and hurt the lower part of the back, but made no mention of this until a year after manipulation, when she returned. The sacro-iliac pain was entirely cured, but the lumbosacral pain had returned three months after manipulation, and on examination she was found to have a typical lumbosacral strain. Further mobilisation has now been attempted by stripping the soft parts from the fifth lumbar spine and excising it, a method which has already been successfully employed.

It seems impossible to produce sufficient movement at the lumbosacral joint by manipulation to cure the condition. The alternative treatment is to immobilise the joint by means of a spinal support or by spinal fusion, as suggested by Hibbs and Albee. The characteristic hyperextension pain may be due to contact between the fifth lumbar and first sacral spines.

TABLE VII.—Spinal Arthritis with Secondary Sciatica.

Total cases—8. (M. 4, F. 4.)		
A—Improved	“Cured”	2 4 = 50%
	“Improved”	2 4 = 50%
B—Not improved	“Unchanged”	4 4 = 50%
	“Worse”	0 0 = 0%

Of the four cases in Table VII. classed as “not improved,” three underwent excision of the lateral lumbosacral joint and fourth and fifth intervertebral joint on the affected side. Of these one was cured, and two improved. The remaining case, a woman of 68, stated that she was a little improved, but still has pain in the back, which is relieved by daily massage at home. Of the four improved cases, two had saline injections into the sciatic nerve in addition to manipulation; in one there was a recurrence of pain in the opposite leg six months after manipulation, which disappeared after complete dental extraction. Patients in this group usually come complaining of “sciatica.” On examination there is tenderness over the sciatic notch and sometimes along the course of the sciatic nerve. All movements of the lumbar spine are limited, and the erector spinae is in spasm; X ray shows lipping of the vertebral bodies, and in some cases of the articular processes, although to show the latter it is necessary, as Putti has pointed out, to have stereoscopic X rays. Other causes of sciatica having been excluded, and septic foci eradicated,

treatment is directed to the spine in the first instance, and full mobilisation appears in some cases to be able to lessen the pressure on the nerve roots which is the cause of the referred sciatic pain. Adjuvant measures in the form of radiant heat, massage, and exercises are also given and, if the pain is not relieved, excision of the lateral articulations above and below the fifth lumbar vertebra with consequent decompression of the emerging nerve holds out good hope of success. Massive saline injections may be of some value. A number of patients in this group have expressed the opinion that the exercises they were taught keep them free from pain.

A male, aged 53, a theatre box-office clerk, caught cold 16 months previously and was laid up for 14 days with right-sided sciatica. This has been painful ever since, and there was an exacerbation five weeks ago on lifting a heavy object; since then he has been off work. On examination maximum pain and tenderness were localised to the right sciatic notch; pain radiated down the course of the sciatic nerve to the external malleolus and at times was felt along the distribution of the fifth dorsal. The right erector spinae was in spasm; lateral flexion to the left was not possible, and flexion was limited. X ray showed lipping of the lumbar vertebral bodies. The back was manipulated on March 30th, 1928; saline was injected into the sciatic nerve on April 16th, and again on April 24th; the back was manipulated again on April 29th, and he continued to have massage and exercises for four weeks, but returned to work in a fortnight. In October, 1929, he reported himself “practically cured,” and added “prior to being admitted to hospital I was hardly able to crawl about; when I came out I was as straight as a guardsman . . . I ache fairly frequently on the right side of the ribs near to the spine, but I find by carrying out some of the exercises that I was put through when being massaged I get rid of the pain.”

TABLE VIII.—Spinal Arthritis without Sciatica.

Total cases—5. (M. 4, F. 1.)		
A—Improved	“Cured”	0 2 = 40%
	“Improved”	2 40%
B—Not improved	“Unchanged”	3 3 = 60%
	“Worse”	0 0 = 0%

Of the three cases in Table VIII. classed as “not improved” one had scoliosis, and manipulation was only done to obtain the maximum amount of correction before fitting a spinal support, after which he was considerably improved; one had massage and exercises for two weeks only and has been unable to continue through other illness, and one, who lived at a distance, had no after-treatment after leaving hospital and has not since returned; in this case gas alone was used as the anæsthetic for manipulation. Clinically these cases give a history of gradually increasing pain in the back, worse after lying or sitting still for any length of time. The whole spine is stiff, and there may be tenderness and spasm of the erector spinae. X ray shows arthritic changes.

A male, aged 58, a coach painter, noticed pain in the back for six years, of gradual onset with no history of injury; the pain was felt across the lumbar region and in the right loin. He had been kept off work for a month. On examination the lumbar spine was very stiff, but there were no definite points of tenderness. X ray showed osteo-arthritic lipping of the lumbar vertebral bodies. The back was manipulated on Feb. 2nd, 1928, and he had massage and exercises for a month. After this he still had some pain and was fitted with a spinal support; he returned to work four months later and now only has pain at times.

Mobilisation appears to be the best treatment for this group, provided efficient after-treatment can be given to maintain it. The alternative is to produce relative immobilisation by means of a spinal support.

TABLE IX.—Neurotic Spine.

Total cases—4. (M. 0, F. 4.)		
A—Improved	“Cured”	0 0 = 0%
	“Improved”	0 0 = 0%
B—Not improved	“Unchanged”	3 3 = 100%
	“Worse”	1 1 = 25%

Pain in the back is only one of the many complaints made by the women comprising this group (Table IX.). They have usually attended many other departments

of the hospital and have had more than one operation. When examined they present a widespread tenderness both on superficial and deep palpation over the whole of the back, but the spine is quite flexible; despite their complaints they are generally well nourished and appear healthy. Manipulation is unlikely to produce improvement and is only justifiable when it appears that there has been a strain which forms the underlying basis of their condition. Massage and exercises are also useless. Vigorous faradic stimulation may be of some help, and the more vigorous it is the better they like it; if allowed, they will continue such treatment for years, and they are always willing to describe at length their various pains and the different types of treatment they have undergone. The one patient in the whole series who said she was worse as a result of manipulation wrote six years later: "the pain in the lower part of my back is incessant. Night and day I get no rest from pain." She was re-examined and appeared a strong, healthy woman; she was doing her house work. She still had diffuse tenderness over the whole of the back, but the spine was quite flexible despite the fact that X ray showed a certain amount of osteo-arthritis lipping of the lumbar vertebral bodies.

I have purposely made no references to the very considerable literature on the subject, as I wished to arrive at an unbiased opinion of the value of manipulation based on my own observations on this series of cases.

Summary and Conclusions.

1. In chronic back strain and sacro-iliac strain manipulation is successful in about 90 per cent. of cases, and where there is evidence of definite exciting trauma success may be anticipated in almost all the cases.

2. Cases of lumbo-sacral strain are not permanently improved by manipulation.

3. Spinal arthritis, with or without secondary sciatica, should be treated in the first place by manipulation and exercises; improvement may be expected in about half the cases.

4. Cases of neurotic spine do not respond to manipulation unless there is an underlying strain.

5. Manipulation of the back should not be confined to cases where there is mechanical displacement, but should be more widely practised with the reservations stated above. It must be followed by efficient after-treatment.

It is with very great pleasure that I acknowledge my thanks to Mr. Blundell Bankart for permission to publish these results, and for his continued help and interest in their compilation.

PROVINCIAL EYE HOSPITALS.—Worcester City and County Eye Hospital last year attended to 3956 patients, an increase of 650; in-patients numbered 203. Seven artificial eyes and 1232 pairs of spectacles were supplied.—The Eye, Ear and Throat Hospital for Shropshire and Wales (Shrewsbury) reports its busiest year. There were 7155 cases (in-patients 1441), an increase of 315. The great majority of the patients—3061—suffered from affections of the eye and errors of refraction; 1640 were treated for nose and throat affections, and 723 from diseases of the ear. In the isolation ward 23 cases of ophthalmia neonatorum were treated.

BIRMINGHAM DENTAL HOSPITAL.—Owing to the decision to synchronise the hospital with the calendar year the annual report covers 15 months. In that period over 15,000 patients were treated, an increase of nearly one-third upon the last comparable period. There were nearly 14,000 anæsthetic cases, which showed an almost identical increase. The filling of teeth, which is done entirely by students under qualified supervision, had also grown materially. The surgical committee states that there is room for more students, and expresses the hope that "fresh and keen spirits, especially from public schools" will be forthcoming. It is added that every care is taken by the university authorities to ensure thoroughness in the training of dental students.

A NOTE ON CERTAIN ASPECTS OF THE EPIDEMIOLOGY AND MORBIDITY OF YAWS.

WITH SPECIAL REFERENCE TO FAT METABOLISM.

By J. O. SHIRCORE, M.B., CH.B., M.R.C.P. EDIN.,
DIRECTOR OF MEDICAL AND SANITARY SERVICES,
TANGANYIKA TERRITORY.

IN considering the epidemiology and morbidity of yaws in Tanganyika Territory it may be convenient if I preface my remarks with a brief account of the geography and population of the Territory, and give a table of the numbers and distribution of the cases treated.

Tanganyika Territory is that portion of Eastern Africa bounded on the north by Kenya and Uganda, the east by the Indian Ocean, the south by Portuguese East Africa and Nyasaland, and on the west by North-West Rhodesia, the Congo, and the territories of Uranda and Urundi. Its total area is about 365,000 square miles, which includes some 20,000 square miles of water. Along the coast lies a plain, varying in width from 10 to 40 miles, behind which the country rises gradually to a plateau constituting the greater part of the hinterland. This plateau falls sharply from a general level of 4000 ft. to the level of the lakes (Tanganyika, 2590 ft.; Nyasa, 1607 ft.), which mark the great Rift Valley extending northwards to Lake Naivasha. The climate varies greatly according to the height above sea-level. Roughly four climatic zones can be distinguished, though even among these there are considerable local variations.

Four Climatic Zones.

(1) The warm and rather damp coast region with its adjoining hinterland. Here conditions are tropical, though not unpleasant except just before and during the rainy seasons when the heat is trying and the atmosphere humid. The average temperature is 78°F.

(2) The hot and moderately dry zone between the coast and the central plateau (300–2000 ft.). This zone is characterised by low humidity, less rain, and a temperature rather lower but with greater daily and yearly variations.

(3) The hot and dry zone of the central plateau between 2000 and 4000 ft. The climate of this zone differs greatly in parts, but its prevailing characteristics are low humidity, moderate rainfall, a fairly high mean temperature with great daily and yearly variations, sometimes exceeding 36°F. daily.

(4) The semi-temperate regions around the slopes of Kilimanjaro and Meru, of the Usambara Highlands, the Ufipa Plateau, and the mountainous areas of the south-western area (4000–10,000 ft.). Frosts occur at the higher altitudes, and the nights are cold.

There are two well-defined rainy seasons annually. Generally speaking, the long rains begin in February or March and last for two or three months, while the short rainy season extends from October to November, but the rainfall is low for a tropical country, and droughts are not infrequent. The total native population is estimated at 4,310,000.

Variations in Incidence.

In the medical report of Tanganyika Territory for 1925 brief notes were given of the comparative incidence of yaws in the different parts of the territory, and the statement was made that there was "an irregularly shaped area comprising the plateau highlands of Iringa, Tabora (north of the Ugalla river), and Dodoma, wherein the incidence is low." There are naturally pockets, in other places, where somewhat similar conditions hold. In the remainder of the territory the incidence is high, with similar pockets of lower or higher incidence. Although some have suggested that insects and indirect contact through wearing infected clothes may convey the infection,

yaws is, in fact, almost entirely a direct-contact disease. The annual medical report for 1924, containing a table showing the sex incidence of 13,619 cases, indicates that, where the district population is undisturbed to any extent by emigration and immigration, the sex ratio for practical purposes is equal. The factors that modify the ratio are the movements of large numbers of male labourers, unaccompanied by their wives, who pass through treatment centres en route to the various plantations, and the fact that males are better able than females to undertake long and arduous journeys for the purpose of obtaining treatment. I am, however, strongly of the opinion that in those districts where scabies is common the abrasions caused by scratching offer increased facilities for the spread of infection. Water in many places is scarce during the dry season, and personal uncleanness also has a good deal to do with infection. In the areas referred to above the incidence, in my belief, varies with the altitude, rainfall, fertility of soil (which depends on the geological formation), the amount and quality of the foodstuffs, the level of the culture of the people, and directly with the distribution of the tsetse-fly.

The outstanding features of the higher altitude plateau, from 3500 ft. upwards, are healthier climate, good rainfall, and freedom from tsetse-fly over vast areas, which allows the breeding of cattle. (This is not to say that all higher altitude areas are free from tsetse-fly.) The population of these areas have therefore an ample and well-balanced diet, including meat, a variety of vegetables and milk and its products; therefore the necessary intrinsic and accessory factors for the development of a robust disease-resisting constitution are supplied. Not only is there a low incidence of yaws in these regions, but advanced tertiary lesions are much less frequently observed. Compare these conditions with the lower altitude areas of poor soil and rainfall, where annual periods of partial famine occur, where little animal protein, less fat, and no milk are available, where large areas are fly-ridden and the population lives from one year's end to another largely on rice or cassava. The same areas coincide closely with the distribution of hookworm, where the health of the population as a whole is below par, a high incidence of yaws exists, and gross tertiary lesions are very prevalent. A point of interest is that when natives of the low-lying areas of high incidence are found in employment in the coastal towns, such lesions as they show do not as a rule progress but stay dormant, a fact which may be attributed to the richer and regular nourishment available, hygienic surroundings, and personal cleanliness.

Table showing the Number of Cases of Yaws Treated over a Period of Four Years in the Various Provinces.

Province.	Area sq. miles.	Population in thousands.	Cases treated during 4 yrs. 1924-27	Altitude.		Tsetse-fly.
				Above 2500.	Below 2500.	
Bukoba	11,000	329	14,545	15,545	—	++
Central	38,078	506	25,068	12,046	13,622	++
Eastern	26,320	432	82,585	—	82,585	+++
Iringa	37,527	341	24,647	1,400	23,247	++
Kigoma	59,816	260	16,700	15,700	—	++
Lindi	37,353	418	65,320	—	65,320	+++

	363,518	4,319	318,125	93,806	224,319	

Effects of Low Diet.

It would appear from the above data that low dietetic values, in particular the scarcity of animal protein, and the almost entire absence of fat, milk, calcium, and fat-soluble A, which are intimately associated with calcium metabolism, are the distinctive

factors which play an important part in the morbidity and epidemiology of yaws. And when yaws obtains a hold on the human organism and is untreated, one might well speculate whether the late tertiary manifestations, the osteoporotic lesions, may not be a result of the breaking down of calcium reserve, by an interference of *S. pertenue* with fat metabolism and the activity of fat-soluble A, in the circumstances mentioned.

This seems to support the views of Willaman quoted by Berg in his book entitled "Vitamins," (p. 210).

"The various yeasts and micro-organisms are able to synthesise A for their own needs and are therefore independent of supplies from without. Very interesting therefore is the statement of Willaman (if correct) that certain fungi, and notably *Sclerotinia cinerea*, appear to need a supply of A, being otherwise incompetent to form spores. We must assume that, just as in the case of animals (which are all parasitic upon the plant world), the parasitic mode of life of these fungi has led to a degeneration of the parasites in this respect, so that they are no longer competent to satisfy their need for A by independent production, and are compelled to draw upon the stores of the host."

UTILISATION OF IMMUNITY IN TREATMENT OF CANCER.

By J. C. MOTTRAM, M.B. LOND., D.P.H.,

DIRECTOR OF THE RESEARCH DEPARTMENT, RADIUM INSTITUTE, LONDON.

THE subject of cancer immunity has a large literature. Woglom,¹ reviewing the subject in 1929, dealt with 000 papers and used 20,000 words. I cannot do better than quote one of his opening statements; he says "Of these 000 communications a small number are of permanent value, many record unconscious and unnecessary repetitions of previous experiments, and far too large a proportion are ridiculous, for few investigators seem to realise that cancer research is a discipline requiring some apprenticeship and that not everyone with an inoculating needle and a dozen white mice can plunge in and emerge with a discovery." Nevertheless, a short statement is here made in the hope that it may be a help to those contemplating the treatment of cancer patients from the point of view of cancer immunity.

Nothing has been found in cancer immunity analogous to the immunity of bacteriology. Specific antibodies are unknown. Cancer immunity relates entirely to inoculated cancer. There is no evidence, apart from the rare disappearance of spontaneous tumours, that there is any immunity against a spontaneous tumour once it has occurred. Immunity against cancer inoculation can be effected by the inoculation not only of tumour material, but also of normal tissues; practically all tissues are effective. It appears, therefore, that cancer immunity is no more than immunity against a strange tissue, and that inoculated cancer obeys a general law covering the transplantation of tissues from one animal to another, whether normal or cancerous. Just as an animal cannot be immunised against its own cells, so it cannot be immunised against its own cancer. The growth of an inoculated tumour frequently results in immunity, so that after removing the tumour by operation, the animal is found resistant to a second inoculation. Similarly, destroying an inoculated tumour in situ instead of removing it by operation—as, for instance, by X rays or by injecting into it various drugs—frequently leaves the animal resistant to a subsequent inoculation. There is, however, not the smallest reason for anticipating any such resistance in the case of spontaneous tumours similarly treated. It has been claimed that immunity against cancer inoculation can be effected by the inoculation of cancer cells which have had a lethal dose of radiation. Assuming that this is true, there is, however, again

¹ Cancer Review, 1929, IV., 129.

no reason to believe that any benefit will result from treating patients by removing their spontaneous tumours, radiating them in vitro and returning them by inoculation into the patient. Nevertheless, this treatment has been advocated and carried out on patients.

Experimental Results.

It seemed desirable to try this treatment experimentally on tumours produced by tar in mice. A hundred mice were taken, depilated and scarified at the nape of the neck. Tar was applied twice a week down the middle line over a distance of half a centimetre. After two months 45 mice remained alive, the high mortality being due to an epidemic of enteritis. Warts, cutaneous horns, and epitheliomas began to appear after four months. As soon as a cancer was present, accompanied by invasion of the subcutaneous tissues as evidenced by an easily palpable mass of growth beneath the skin, the diseased area was removed by operation and small pieces taken from the base of the growth were inoculated into the right and left flanks. When both these grafts had grown into measurable tumours, one was removed by operation, cut into small pieces, and exposed to a lethal dose of X rays. The exposure to X rays was kindly carried out by Prof. Russ at the Middlesex Hospital. The radiated tumour was finally inoculated into the mouse. The growth of the other graft was then watched to see whether the inoculation of the radiated tumour effected it in any way. Only six mice survived these long and severe experimental procedures. In some cases the grafts did not grow, or grew on one side only; in others the wound became infected, or the primary growth recurred and killed the animal.

The following table gives the histories of these six mice; the figures represent days.

First operation.—Removal of primary tumour, graft placed on either side.
Second operation.—Removal of a graft radiation and re-inoculation.

* Graft grew one side only.

† Replaced on both sides.

The growth of the graft left behind at the second operation before and after the inoculation of the irradiated tumour constitutes the test; this information is given in the chart, where it is seen that the growth is progressive in the case of animals 1, 2, 4, and 5, and that there is no evidence of any retarding influence as a result of inoculating radiated tumour

tissue. In mouse 3 there was a period of regression on the seventieth day, but this was associated with pregnancy, and when the young were born and removed growth at once again became progressive.

The chart shows the growth of the auto-grafts before and after the animals were treated with radiated tumour emulsion. Arrow = radiated tumour inoculated; Pr. = pregnant; Y = young born; U = tumour ulcerated.

In mouse 6 the tumour was a slow-growing and variable one, but on the whole growth was not altered by the treatment. In this mouse extensive central necrosis of the tumour was present and accounted for the quick fluctuations in the size of the tumour. It is concluded, therefore, that the treatment had no effect on the growth of the grafts.

Discussion.

Although the experiments are entirely negative, it seems desirable to publish them in detail because treatment of patients along these lines has been tried, and is being recommended. For reasons given in the introduction, all treatment of patients based on experiments with inoculated cancer are open to the criticism that human conditions are not reproduced in inoculated cancer, but it is possible to carry out experiments with spontaneous tumours in animals, as has been done here, and until this has been done and shown to be effective trials on patients are not justifiable.

The cancer cell does differ from the normal cells of the host, and this very difference enables one to postulate the possibility of cancer immunity set up in an animal against its own tumour, although so far it has not been demonstrated.

Conclusion.

The treatment of mice bearing spontaneous tumours by the inoculation of irradiated tumour has no influence on the growth of these spontaneous tumours. Results obtained with inoculated cancer do not justify the treatment of cancer patients in a similar manner.

Clinical and Laboratory Notes.

A METHOD OF ESTIMATING THE RATE OF FLOW OF BLOOD THROUGH CAPILLARIES.

BY I. HARRIS, M.D. KÖNIGSBERG,
HON. PHYSICIAN, LIVERPOOL HEART HOSPITAL.

THE determination of rate of blood flow is of great practical importance. In recent times it has been more and more realised that the peripheral circulation plays an important part in heart failure, and stasis and cyanosis largely depend on the rate of flow in the peripheral circulation. As an example of the importance of the rate of flow in practical medicine I will mention the work of Eppinger and his co-workers, who brought forward convincing evidence that cardiac asthma is due to acceleration of blood flow in the peripheral circulation. They also found that morphia slows the circulation and accordingly recommend this drug for cardiac asthma. From my own experience I can testify to the usefulness of morphia in this type of cardiac affection. Obviously the time it takes for the blood stream to traverse the course from the arteries to the veins is the most vital fact in the solution of the majority of the problems of circulation, and it is particularly vital in cases of high

The upper wave is the radial pulse; the lower is the manometer record. x Signifies the time when the venous pressure rises. Time in fifths of a second.

blood pressure. The following method has been employed to estimate the time from the moment the blood stream leaves the arteries to that of reaching the veins.

The armlet of a blood pressure apparatus is placed on the arm. Lower down the basilic vein is connected by means of a needle and tubing to a water manometer. On the wrist the pad of a McKenzie's polygraph is placed on the radial artery and connected by means of rubber tubing to one of the pens of the instrument. The water manometer is also connected by tubing to another pen of the polygraph. The two pens are placed in such a position that their movements can be photographed by means of an apparatus such as is available on the electro cardiograph, to which also a time-marker is attached. Air is now pumped into the armlet, and the pulse completely obliterated. The level of the water manometer connected with the vein will now remain stationary. The pressure in the armlet is suddenly released, but sufficient pressure is left to prevent circulation in the veins of the arm. The pulse-wave which now passes through the radial artery will be automatically recorded on the photographic plate. An appreciable time afterwards the pressure in the water manometer will rise, which will also be recorded automatically on the same plate (see Figure). All that is necessary now is to ascertain the duration of the interval between the appearance of the pulse and the rise of pressure in the water manometer.

A more suitable method which, however, requires special apparatus, is as follows. A drum covered with photographic paper is placed in a box with a slit; the drum is rotated by clockwork. Opposite to the slit is placed the water manometer, a time-marker, and a pen connected by a pad to the radial pulse. Better photographic results are obtained if a cork is allowed to float on the water of the manometer.

It is, of course, necessary to take the ordinary precautions against coagulation.

That this method is reliable is seen from the fact that repeated examinations of the same patient, under similar conditions, give approximately the same results, and that variation of the flow of the blood in the arm, brought about by the application of hot water or ice, gives readings which show an acceleration or slowing respectively of the rate of flow of the blood through the hand.

The same method can be used at the same time for estimation of the cardiac output. The number of beats allowed to pass through the armlet is recorded on the photograph. All that is necessary is to ascertain from the manometer the rise of the water column. It will, of course, be found that the rise in the pressure stands in definite relation to the number of beats permitted to pass through the armlet.

A CASE OF CÆSAREAN HYSTERECTOMY FOR FIBROIDS ASSOCIATED WITH CONGENITAL RECTO-VULVAL FISTULA.*

BY A. M. CLAYE, M.D. LEEDS, F.R.C.S. ENG.,
OBSTETRIC SURGEON TO LEEDS MATERNITY HOSPITAL; ASSISTANT
SURGEON TO THE HOSPITAL FOR WOMEN, LEEDS.

A PRIMIGRAVIDA, aged 34, first attended the antenatal clinic at the Leeds Maternity Hospital on Oct. 16th, 1929.

There was no previous medical history of note; menstruation had always been regular, 3/28, not excessive. The course of the pregnancy had been normal except for a fortnight's heartburn and sickness immediately prior to booking. She was about 26 weeks pregnant. On inspection of the vulval region there was a pigmented impervious depression at the normal site of the anus, and the lower end of the bowel opened into the vulva just behind the posterior margin of the hymen. Control of the bowels had always been good except when there was diarrhoea; at these times there was occasionally incontinence. On digital examination the opening gripped the finger.

(When seen on Feb. 13th, 1930, the patient had been in labour four hours and the membranes were ruptured; there were several fibroids palpable abdominally, the largest being on the left side, about half the size of a cricket ball, and soft. On rectal examination another fibroid of the same size was felt in the pouch of Douglas. The head could not be pressed into the pelvis. I decided to do Cæsaean section.

On laparotomy the two fibroids specifically mentioned were seen, and several smaller ones. That in the pouch of Douglas was adherent to the rectum. The adhesions were separated and after Cæsaean section and delivery of a live male child, weighing 6 lb. 6 oz., subtotal hysterectomy was performed. The patient made an uneventful recovery, and the baby did well.

I can find very few references in the medical literature to recto-anal deformities associated with labour. O. Smiley¹ reported a case of Mother with Imperforate Anus delivered of Normal Child in the United States in 1911. The rectum opened into the vagina 2 inches from the vaginal orifice. The patient was a primigravida of 27; she also had hypospadias. Delivery was effected with the forceps on account of delay. There was retention of urine for 30 hours afterwards, and attempts at catheterisation failed; the condition was relieved by the injection of 2 per cent. boric acid into the bladder, 21 oz. of urine

* Read to the North of England Obstetrical and Gynaecological Society on April 11th.

¹ Jour. Amer. Med. Assoc., 1911, iv, 2047.

being passed 15 minutes later. The patient developed sepsis, the temperature being raised, with offensive excessive uterine discharge, from the third to the twelfth day; subsequently the condition settled. In 1925 P. R. Cooper² reported a case of Labour with Vulval Anus: Prevention of Vulvo-anal Rupture. The anus was in the same situation as in my case—i.e., the common type of congenital fistula was present. The patient was a primigravida of 24. When the head began to appear, it was thought certain that a rupture of the ano-vulval diaphragm would occur unless steps were taken. A right episiotomy was done, which after suture subsequently healed by first intention; the ano-vulval membrane was undamaged. E. C. Brenner³ in a paper on Congenital Defects of the Anus and Rectum quotes Morgagni as reporting the case of a woman who lived a hundred years, bore several children and never knew of her abnormality. The reference in Morgagni was turned up for me, but no mention of the fact that the woman had borne children could be found.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF MEDICINE.

A MEETING of this Section was held on April 25th, with Dr. R. A. YOUNG, the President, in the chair.

CHRONIC ARTHRITIS TREATED BY GANGLIONECTOMY.

Dr. L. G. ROWNTREE (Rochester, U.S.A.) gave a cinema demonstration of the results of treating chronic arthritis by ganglionectomy. Eighteen such operations had been performed at the Mayo Clinic, he said, on 17 patients. The most encouraging results had been obtained in the chronic cases of arthritis deformans without marked osseous change. He related the case of a young woman who was told by the physicians that she must spend the remainder of her life in bed. She had had arthritis for six years, and was incapacitated, though she was the wage-earner of the family, her mother being an invalid. Dr. Rowntree reasoned that everything done for chronic arthritis had the effect of increasing the circulation and warming the joints; this was true also of treatment for Raynaud's disease. It seemed that such an increase of warmth and circulation was all that was needed to relieve the pain of chronic arthritis. In this case the patient's joints were cold, clammy, and the pain was worse in a storm. Two and a half years after ganglionectomy, however, there was nothing the matter with her legs, and she was walking well. Within six weeks of the operation she was without pain, and had perfect control of her legs, but there was still a good deal of arthritis in the upper extremities, and the pain of this robbed her of sleep. When she tried to raise her arms she had tremor, and there was muscular atrophy of the hands, with much swelling over the knuckles. Therefore the last cervical and the first two dorsal nerves were removed, all the rami being cut. After the operation she was able readily to raise both her hands over her head, and there was no tremor nor pain; there was good movement of the hands, and the atrophy was disappearing.

A girl, aged 16, had cold, clammy feet and painful ankles and knees. She was two months in the wards of the hospital and had previously had eight months of medical treatment elsewhere. Four weeks after ganglionectomy she was trying to walk and there was no more pain. In six weeks she was able to walk without any help; later she was dancing, and returned to school. The legs were still somewhat weak, and there was a little deformity of the spine, which he did not touch.

A woman, aged 44, had a subacute arthritis with fever and anaemia. Six months of ordinary treatment brought no improvement. In May of last year ganglionectomy was done for disability of the upper extremities, and immediately after the operation her fever disappeared and never returned. No further transfusions for her anaemia were carried out after the operation. She asked to be operated upon for the condition in her feet, but this was declined.

A man, aged 20, had osseous arthritis of 12 years' standing. He had a loudly clicking hip with extreme pain. All treatment tried in the course of 12 years failed and five weeks' further treatment in the hospital had no effect. In him the operation achieved nothing except relief of pain in the feet, the main seat of trouble being the hip.

A woman, aged 23, had been ill for 11 years, and had had treatment by autogenous vaccines and otherwise. She screamed whenever she was moved, and very little movement was possible in the legs; radiographic examination under an anaesthetic indicated that her legs were ankylosed, for they could not be flexed. The operation gave her more movement and relieved all the pain in her feet and ankles; the pain in the right hip greatly diminished. In less than three months after the operation she could walk alone, with the aid of a stick. Nine months after the operation she was walking all about the house, with very little pain. Dr. Rowntree thought this patient still had a long way to go, but she could make the journey. Evidently the ankylosis was fibrous, not osseous.

After describing and depicting a number of other cases Dr. Rowntree said that a marked increase in muscle tone and in strength was always noticeable after the operation, along with disappearance of the deformity and the trophic changes. Ganglionectomy was not a panacea; the cases had to be very carefully selected—namely, those with cold, clammy hands and feet, and conspicuous sweating. Results were best in the young. The joints most benefited by the operation were the hands, feet, ankles, and wrists. The improvement in knees and elbows came about more slowly but was definite. The shoulders and hips did not give such good results. Where there was much osseous change the condition did not seem to get much better during the period the patients were under observation. But in the cases most suitable the results deserved the term miraculous. There had been no deaths in this series.

The abdominal approach to the ganglion was of the type described by Hunter and Royle. There had been no difficulty in the operation, except that two patients had had a mild illness, following upon an intestinal disturbance after the operation. Sometimes this took the form of stasis, sometimes diarrhoea. After the initial incision the ganglia were in view in front of the surgeon, and could be removed en bloc without any difficulty. Dr. Adson, who did the operations, hesitated for two years about operating for disability of the arms, for he was not quite certain what should be done. He made, for this, the posterior approach, cutting through the upper ribs and exposing the last cervical and first and second dorsal, and removing them en bloc. The only complication from this was in the case of a woman who had pleurisy for a few days. Though the operation was one of considerable magnitude, and should only be done by neurological surgeons, it should not cause them undue anxiety. Nothing morphologically wrong with the tissues could be detected in these cases and he had seen many ganglia removed in animals apparently without any untoward effect. Nor was there any cardiac insufficiency after the operation.

Some of the above statements were made in answer to questions, and at the end of the demonstration the PRESIDENT commented on the satisfaction which would be felt that something could now be done to help these sorely afflicted people. It was surprising how many parts of the body could be dispensed with.

Prof. W. E. DIXON, F.R.S., and Dr. G. N. MYERS contributed a paper on the

CURATIVE ACTION OF DIGITALIS IN TOXAEMIA.

Prof. DIXON said the work was done to discover whether digitalis was valuable in pneumonia, a matter on which opinion was divided. Some said that if digitalis was used in pneumonia, the patient was more

² Clin. Jour., 1925, iv., 155.

³ Surg., Gyn., and Obst., 1915, xx., 579.

liable to die, while others produced statistics to show that more patients were cured of pneumonia when digitalis was given than when it was not. In nearly every fatal case the death was from toxæmia. Like all microbial infections pneumonia produced a condition of shock, shown by a gradual fall in blood pressure and an enormous dilatation of the splanchnic area; the heart continued to beat normally, and the central nervous system remained active. The shock might, therefore, be due to an action on the central nervous system.

For the experiments diphtheria toxin was ultimately the one selected, on the ground that the dose could be accurately measured; 1/350th of a cubic centimetre killed 95 per cent. of the guinea-pigs which were injected with it. There were two groups of experimental animals; both received the toxin, and one group also had digitalis under certain conditions. Hundreds of tests showed conclusively that if a reliable tincture of digitalis was given to animals they survived subsequent injections of bacterial toxin, even if three times the minimum lethal dose of toxin was given. The same effect was obtained if the toxin was injected first, so long as the use of digitalis was not much delayed. The glucosides from digitalis and strophanthin also showed a life-saving effect, though not to the same extent as that seen after digitalis. The other substance, ouabain, which was used in America as a standard for their digitalis, was a glucoside belonging to the same group, and it was the only one which could be weighed out accurately. It acted as an ideal control because it was valueless in toxæmia, though within a few hours it acted on the heart in the same way as digitalis. Animals which received ouabain died more readily than did those which received the toxin alone. Strophanthus acted quickly on the heart—i.e., it had the action which the physician desired in pneumonia—but if it were given to animals for two days it had no beneficial effect in curing the toxæmia; it must be given for some length of time for this to happen. Given this condition, strophanthus was almost as good as digitalis.

Digitalis had a negligible effect on the leucocytes in normal animals, but digitalised animals showed a decided leucocytosis. It seemed that digitalis, in taking time to act, occupied some portion of the cardiac structure to which the toxin normally attached itself. If digitalis was given to the heart first, the toxin was without effect; but if the toxin was put in first and was allowed plenty of time to act, digitalis afterwards had no effect. Digitalis did not act any more quickly on injection than when given by the mouth. Large doses were required to cause any alteration in the T-wave of the electrocardiogram. This research encouraged the idea that there might be other drugs which might limit or check the activities of pathological organisms in the body. Some hydrologists had recently claimed that the waters of their spas had an antitoxic or detoxicating effect on certain bacterial infections.

MEDICO-LEGAL SOCIETY.

At a meeting of this Society on April 21th, with Lord RIDDELL, the President, in the chair, a discussion took place on

GONORRHOEA FROM THE MEDICO-LEGAL POINT OF VIEW.

Dr. KNYVETT GORDON, in opening, said his object was to clear up some of the difficulties apt to arise when a case of gonorrhœa emerged from the doctor's consulting room into the solicitor's office or a court of justice. His remarks were based upon the examination of some 7000 specimens from cases of suspected gonorrhœa, and upon experience as a witness in courts.

In the male, when the gonococcus gained entry into the genital organs, the inflammation was accompanied by a discharge, which might be either profuse or

so scanty as almost to escape notice. In either case the organism might be confined to a small part of the urethra, or it might get into recesses and glands and lurk there for a long time, its dislodgment being very difficult. The man might then have no discharge, and, under the belief that he was cured, he might marry, and so infect his wife. The female canal had even more recesses and glands than the male, and the organism got into the oviducts, which at their further end opened into the general peritoneal cavity. Thus in women not only was the disease more difficult to cure, but the gonococci were less accessible to the pathologist. If the organism entered the eye, the intense inflammation might lead to blindness; probably half the complete and incurable blindness of babies was caused by contact with the gonococcus in the passages of the mother during birth. One of the complications of the disease was rheumatism and a very definite accompaniment was intense mental depression.

The Social Significance of Gonorrhœa.

It was quite common for an attack of gonorrhœa in the male to be regarded as of little present and almost negligible significance in the future, and as easily curable in any case. This was because after a time the discharge might cease, even when there had been no treatment. Dr. Gordon, however, believed that real cure was even more difficult than in syphilis. For obvious reasons, the fact of having gonorrhœa was often concealed by the patient, so that no doctor was consulted; even if medical treatment was sought, attendance ceased when there was no further discharge, though at this stage a cure might be brought about. In the male the gonococcus might attack the spermatozoa factories, the patient being thus rendered sterile for the rest of his life, even when he had passed the stage of infectivity. The effects on the female were even more serious, for the gonococci sealed up the oviducts so that ova could not reach the uterus. Gonorrhœa was now more common than formerly, because illicit sexual intercourse was no longer synonymous with prostitution, and unmarried women were no longer divided into virgins intacta and prostitutes. The amateurs were more numerous and more dangerous than professionals—more dangerous because most of them did not know they had the disease. Secrecy of treatment at clinics was relative rather than absolute, especially in country districts. Though from the medical standpoint compulsory notification was easily defensible, he believed that it was impracticable in this country and even if introduced would put a premium on concealment, and thus lead to increased total infection.

Identification of the Organism.

In the male the gonococcus was not difficult to recognise when found, but in the female its discovery was much harder and it had to be differentiated from a number of other organisms which inhabited the genital canal and resembled it. A report on a single swab was valueless for purposes of a decision in court, for an opinion was not proof. The gonococcus was a Gram-negative intracellular diplococcus. In the hands of an expert, Gram's method was entirely reliable, but if carelessly used it might be fallacious. The crucial test of animal inoculation could not be employed, for gonorrhœa could not be communicated to laboratory animals. Two procedures remained: culture and the complement-fixation test. If a positive result was obtained by culture, he believed it was accepted by the court as conclusive evidence of gonorrhœa in the patient, just as it would be accepted by a pathologist. But culture did not always come off, selective media being very sensitive, and a negative result was valueless. The complement-fixation test he regarded as less useful; it gave a positive result in only 40 per cent. of cases of true gonorrhœa, and sometimes a false "positive" was obtained. In addition, it told nothing about the infectivity of the patient. He did not now perform this test.

Infectivity could be determined only by bacteriological tests, and clinical opinion alone should never be accepted.

An important question was whether the finding of the gonococcus was evidence of venereal infection by that disease. In the male one could dogmatically say that if gonococci were found in the urethra, only sexual intercourse could have placed them there, for these organisms were incapable of independent movement. Hence, the infected lavatory must be ruled out as a possible cause, and such an excuse did not prevail with the courts. In the female the case was different. Many women, especially married ones, suffered from a discharge associated with some inflammation of the parts, and both features were indistinguishable from gonorrhoea. Ignorance could scarcely have worse results than where it led to an inaccurate report of gonococcal infection. A case had been heard in the Divorce Court in which the judge ruled that the organisms found were gonococci, though this was against the evidence of bacteriologists; it was also ruled that the woman could only have contracted the disease from her husband, despite the fact that repeated bacteriological tests failed to detect gonococci. On the discovery in young girls of an organism resembling the gonococcus, accusations of rape had been made against innocent men.

A Series of Questions.

There were several questions on which Dr. Gordon sought opinion from legal members. First, seeing how easily the gonococci could get on towels and other articles of common use, was concealment of an attack and neglect to take due precautions an offence? Would it justify dismissal of an employee? The second was, could an unmarried man or woman recover against the other party damages because of alleged contraction of the disease in illicit intercourse? Thirdly, presumably infection of a partner in marriage was a form of cruelty and constituted a ground for legal separation. If the man or woman believed himself or herself to have been cured, what difference did this make in the eyes of the law? If the husband was sterile as a result of an old attack of gonorrhoea, there being no question of infectivity, would this justify a decree of nullity? And in the case of one-child sterility, if a woman forgave infection by her husband before she realised that gonorrhoea had sealed up her tubes, had she a remedy when she learned she could not again bear children? He particularly invited legal contributions on the question of compulsory notification.

Clinical Diagnosis.

Dr. F. J. McCANN agreed that gonorrhoea was not treated by the community generally with the respect its gravity called for. In diagnosis he thought too much reliance was placed on the bacteriologist; his view was that certain cases of the disease could be recognised clinically. If a previously healthy woman suddenly had a discharge, accompanied by local swelling, and pain on micturition, she could be held to be suffering from gonorrhoea, since nothing else caused this group of symptoms. The same was true of a conjoint infection of the cervix, the urethra, and Bartholin's glands; and if tubercle or infection from the bowel could be excluded, double tubal disease meant gonorrhoea in 999 cases out of 1000. The diagnosis of the disease had not yet reached the stage of precision necessary in the witness-box. If one waited too long before taking material for investigation, it was easy for the delicate gonococcus to be overgrown by more vigorous pus organisms. Specimens for this purpose should not be taken from the vagina but from the urethra, and with a sterilised platinum needle. It was very difficult to cultivate the gonococcus. In cases of doubt he thought attention should be paid in court to clinical evidence.

Mr. ERNEST CLARKE remarked that ophthalmia neonatorum was now becoming less in incidence on account of the care now exercised in antenatal clinics, especially when the mother was known to have

the disease. He had often wondered what was the legal position when a healthy woman was married to a man who gave her gonorrhoea and thus caused blindness in her child. Could she obtain a separation from her husband for this?

Legal Views.

Mr. W. G. EARENGEY pointed out that to have gonorrhoea was not in itself an offence, and an infected person who was known to have been neglectful and to have communicated the disease to another could not be brought to justice in a criminal court. An employer could do nothing more than give such infected person notice to leave, or, failing such notice, pay him the money due. When a man imparted the disease to the woman he married, the infection was not cruelty unless he did it knowingly, nor was the woman entitled to separation or other remedy; in other words, it was included in the risk or chance she took when she married. If, however, he knew he had the disease before coitus, the infection was legal cruelty. A husband could not sue his wife, nor a wife her husband for a tort. If a man infected an unmarried woman there would be no right of legal action, for the woman would have to rely on something which was against public policy; it would be against public policy for the court to enforce any imaginary right she might have for damages, because the court would have to consider the circumstances in which the disease was communicated. Nor could a married woman take action against her husband for assault because he had infected her. The wife—unless her consent could be shown to have been obtained by fraud—must be held to have given consent to the act. If, however, after a wife had condoned her husband's fault he again lapsed, that cancelled the condonation, and the previous grounds could then be brought forward. Mr. Earenghey did not see why compulsory notification should not be made part of the law; and if this were done it would naturally become an offence to impart the disease.

Mr. BARRY O'BRIEN remarked on the importance given in the courts to proof of infidelity on the part of a husband or a wife. If a woman brought an action against her husband in the Divorce Court because he had a gonococcal infection and he said he had never had intercourse with anyone else since marriage, what support was the medical man able to give to his contention that the man's disease must be a latent infection reawakened?

Mr. W. S. JONES said that surely it was possible to give an employee immediate notice if he contracted gonorrhoea. An employer who did not do so was laying himself open to an action for negligence, for other employees might be infected.

Dr. TEMPLE GRAY said a servant could not be dismissed without notice and without wages except for breaking an implied contract; there was no implication that such servant would maintain himself or herself in a certain condition of health. If such a case occurred in his own household, however, he would risk the consequences and would send the servant away forthwith. He asked whether there was any overt sign by which it could be known at about what date the husband had contracted the disease. If a man could not know when it was safe to marry if he had once had the disease, no such man could ever marry with a clear conscience.

Compulsory Notification.

Dr. LETITIA FAIRFIELD said she almost regretted that the opening paper had been read to an audience containing lawyers, for they might assume it was impossible to be certain that any person had ever had gonorrhoea. For a number of years she had been associated with public health work and after the war she had much to do with starting treatment schemes, when there was a good deal of public ignorance about venereal diseases. In a voluntary organisation she had read many thousands of letters which showed very pathetic results of the spread of these diseases. She hoped that juries would not

place too rigid a reliance on the bacteriological tests when a case was before them; the clinical observations should be given an important place. Only very rarely was infection of girls the result of a criminal assault. She did not think the question of compulsory notification was so simple as would appear from some of the remarks. It was not that one hesitated to bring publicity on the sufferer; nor was it in connexion with acute cases that difficulties occurred, for these people were ill and depressed, and even suicidal, and longed for relief. The difficulties were in the class of case in which proof was not at all easy, however it was approached. The Ministry of Health was against the notification of gonorrhoea, feeling that the disease was already difficult enough to get under treatment, and that under notification there would be a great dread, with consequent concealment. In Sweden, where venereal disease was notified, there had been a great diminution in the incidence of syphilis, but it had not affected the incidence of gonorrhoea. The average attendance at clinics was greater in London than anywhere else, and much more good was done by winning the confidence of patients than by trying to hold the disease in check by compulsory methods.

Dr. ERIC DOBSON thought it seemed clear that, irrespective of the patient's or anybody else's feelings, compulsory notification of every venereal disease would be an excellent course. But how would this affect professional secrecy? Also, what action would lie against the notifier for defamation of character or, in the event of subsequent separation or divorce proceedings, for damages? The practitioner was sure to lose his patient, and the latter would let it be freely known in the district that the doctor had got him into trouble through the notification. Dr. DOBSON agreed with those who said that compulsory notification would lead to greater concealment than at present. He thought members of the medical profession would shrink from notification, for much the same reason as they were now reluctant to have anything to do with mental cases.

Sir WILLIAM WILLCOX said the question of notification was very difficult, and he did not think it was likely to come into force in this country. The doctor who notified was in an unfortunate position; he was liable to legal action and much expense and anxiety therefrom. "Once notified, always notified"; it would be a life sentence, and the patient would be looked upon as a sort of social leper.

THE PRESIDENT said he did not believe Parliament would sanction notification, which would be objectionable from many points of view. Recently the Corporation of Edinburgh had brought in a Bill providing for the compulsory treatment of syphilis, and for such a Bill something could be said. But notification was a different matter.

Reply.

Dr. KNYVETT GORDON reminded Dr. McCann that the gist of his paper was not that the pathologist was the only person who could diagnose gonorrhoea, but that he could not be sure of diagnosing it. He had full sympathy with Dr. Fairfield's remarks. In the material sent him from young girls he found the gonococcus in 80 per cent. He did not agree with the principle that if there were three successive negative reports in a case, it could be regarded as cured. In such cases one could with confidence fall back on the physicians. An expert in the use of the urethroscope would probably be correct in 95 per cent. of cases. Dr. Gordon was personally against compulsory notification of venereal diseases, but it was a duty to impress on the public the seriousness of these maladies. He held that prophylaxis should not only be possible, but should be preached.

Rebels and Notices of Books.

OTO-RHINO-LARYNGOLOGY.

Tonsil Surgery. Based on a Study of the Anatomy. By ROBERT H. FOWLER, M.D., Chief Surgeon to the Tonsil Hospital, New York. Philadelphia: F. A. Davis Company. 1930. Pp. 288. \$10.

THE first part of this book is largely concerned with the anatomy of the faucal tonsils, and is accompanied by some excellent plates illustrating dissections of the tonsil and the adjacent structures. These anatomical studies are associated with the investigations of Dr. T. Wingate Todd and the dissections of Mr. Harry Beecher; the principal point which emerges from them is that the deep surface of the tonsil is crossed below its centre by a transverse groove into which is inserted fibres of the palato-pharyngeus muscle, called by the author the tonsillo-pharyngeus. This muscular attachment, which has been observed by others and has been variously described as part of the superior constrictor or a "triangular ligament," is, in the opinion of Dr. Fowler, of great importance; he lays great stress on the teaching that these fibres must not be removed with the tonsil in any form of tonsillectomy. A large portion of the book is occupied by full and well-illustrated descriptions of no less than seven methods of tonsillectomy by dissection, some of them differing from others only in small details. Dr. Fowler himself uses a slow, careful, and delicate method, taking great care to remove no muscle-fibres with the tonsil, and he insists on complete rest for five days before operation. The modern guillotine operation is described as being performed in two ways—by dislocating the tonsil either against the angle of the jaw or with the finger; both methods are given as Sluder's, though the former only is properly his. Willis and Pybus, who first introduced the latter method in this country, are not mentioned. In the discussion of the relative advantages of local and general anaesthesia the conclusion is that the choice depends largely on the training of the surgeon, but that it is better to operate on children under general anaesthesia. No reference is made to diathermy or other methods of treatment, and the book can hardly claim to be a complete treatise on the surgery of the tonsil, for the author does not discuss the treatment of malignant disease nor, except for a brief account of the opening of peritonsillar abscess, any operation except the usual tonsillectomy. A short chapter on evolution quotes largely from the work of Mr. Secombe Hett and Dr. H. G. Butterfield. The clinical aspect of the subject is dealt with in a rather cursory fashion, and the indications for operation are described too briefly. The results of operation are more fully discussed; the author has found strikingly good results in the treatment of rheumatism both in children and in adults, but does not differentiate between the forms of disease included under rheumatism. The book is beautifully produced and the colour plates are excellent.

Nasal Catarrh. By W. STUART-LOW, F.R.C.S. Eng., Consulting Surgeon to the Central London Throat, Nose, and Ear Hospital. London: H. K. Lewis and Co. Ltd. 1930. Pp. 81. 5s.

THE term "nasal catarrh" includes a multitude of diseases, and the author of this little book has used the title in a popular sense to cover an exposition of his views on a variety of diseases of the nose. He holds strong opinions and expresses them with vigour; indeed, the writing suffers somewhat from over-emphasis. The object of the book is to show that nasal catarrh, whether acute or chronic, originates entirely in obstruction to a free nasal passage, and that the removal of such obstruction is of the most urgent importance in its treatment. Although it is generally acknowledged that obstruction plays a

A CHILDE OPERATING THEATRE AT PORTSMOUTH.—A first operating theatre, named after the late Mr. G. P. Childe, a former honorary surgeon, has been opened at the Royal Portsmouth Hospital by his widow. It forms the first part of the contemplated extensions.

large part in the causation of chronic catarrh, we hardly think that Mr. Stuart-Low will have succeeded in justifying the use of the word "entirely" in this connexion, or that the dictum should be applied to acute catarrh. Exception must also be taken to the statement that, in all cases of hay-fever, the nasal interior has been ready for the paroxysm, owing to the lining membrane being chronically congested from the presence of some disturbance of its interior anatomy, such as enlargements, deviations, spurs, polypi, or adhesions. The utmost that the author admits is that some patients are especially liable to nasal catarrh when grass-pollen dust is about, but he does not even mention the general specific susceptibility of such patients as shown by their cutaneous reactions. He does not believe in the treatment of nasal catarrh by vaccines, but is "more in favour of the generation of nascently produced antibodies generated at the immediate site of the inflammatory septic trouble by means of galvano-cautery applied to the roots of nasal polypi, granulations, and cedematous sites;" but he adduces no evidence that such treatment does in fact lead to the production of antibodies, and elsewhere he says that "it is reprehensible to apply the galvano-cautery to the middle turbinal region with risk of olfaction being impaired or lost, or fatal meningitis ensuing." On the other hand, Mr. Stuart-Low deserves all credit for his insistence on the importance of conserving the mucous membrane in intranasal operations. It is unfortunate that the book contains too many unsupported statements to be given whole-hearted acceptance by the specialty.

CLINICAL ASPECTS OF VENOUS PRESSURE.

By J. A. E. EYSTER, B.Sc., M.D., Professor of Physiology, University of Wisconsin; Associate Physician, Wisconsin General Hospital. London: Macmillan and Co., Ltd. 1929. Pp. 135. 10s. 6d.

Prof. Eyster's name is associated with numerous researches on cardiovascular subjects. In this volume he considers the application to clinical medicine of physiological observations on venous pressure, and gives a full bibliography of the more important papers on the subject. Venous pressure may be measured directly by the introduction of a cannula into one of the superficial veins; this method is obviously not applicable at the bedside, where repeated observations are required, for, as the writer observes, it is the trend of variation in pressure, rather than the absolute value, which is of importance in prognosis. The indirect method of estimating venous pressure by determining the applied pressure necessary to produce collapse of a superficial vein in the hand or forearm is fully described. This gives results which are quite equal in accuracy to the direct method and can be applied at the bedside without any inconvenience or discomfort to the patient. In health the venous pressure, with the body at rest in the recumbent posture, is maintained in the neighbourhood of from 40 to 60 mm. of water, variations in venous inflow being compensated for by corresponding variations in the ventricular output. When, however, the heart begins to fail and is no longer able to cope with the venous inflow, the venous pressure rises rapidly to 200 mm., or even higher. This rise, according to Prof. Eyster, precedes the other signs of venous congestion, for which indeed it is directly responsible, and is therefore of importance in diagnosis as well as in following the progress of the case under treatment. A series of case-histories is given to illustrate this point. The highest readings (400-500 mm. of water) are recorded in the Valsalva experiment, which is not merely of academic interest, since it is analogous to the straining at stool and other sudden violent physical efforts which may lead to heart failure. By attracting attention to a simple clinical test, which is rarely employed and may be of considerable value, the author of this book has rendered a useful service.

J. GEORGE ADAMI.

A Memoir by MARIE ADAMI. London: Constable and Co. 1930. Pp. 179. 10s. 6d.

THIS is a brief but replete account of the life of a man of many activities. The book is necessarily uncritical, being compiled and largely written by Prof. Adami's widow, but it nowhere errs on the side of fulsome or indiscriminate praise. The memoir takes us through Adami's successful academic career at Cambridge, and his long experience as professor of pathology at McGill University, notes his brief sojourn in London with high responsibility during the war, and closes with an account of his seven years of active work as vice-chancellor of the University of Liverpool.

Adami knew many members of the medical profession, while every English-speaking pathologist is familiar with his writings, so that this pious memoir will be recalling to many of our readers circumstances which are quite familiar to them. But Prof. Warthin of Michigan points out one thing that may not be generally realised, though it is very true. Adami left a deeper impression, upon the evolution of the philosophy of pathology than he did practically upon its clinical uses and applications. At Montreal he was especially interested, as Sir Humphry Rolleston, an intimate friend, points out in a brief introduction, in bringing his subject into close relation with other branches of science, and this he was specially qualified to do from a long training in scientific biology at Cambridge. And to read a list of his publications, which was steadily added to for over 40 years, is to see how often Adami's views, even if only temporarily useful as supplying working conventions, proved none the less prophetic of the truth.

Mrs. Adami has done well to publish this short history of Adami's activities, and has been fortunate in securing the collaboration of a group of his distinguished friends.

JOURNALS.

LEPROSY REVIEW.¹ Vol. I., No. 2, April, 1930.—H. W. Wade points out that the failure attending isolation in a single colony on the Island of Culion in the Philippines was due partly to inadequate diet with resulting beri-beri, and partly to its being filled early in the century with none but hopelessly afflicted lepers. A new era began in 1921, when the public began to realise that lepers were really being discharged cured. Then, for the first time, early cases began to present themselves voluntarily, and now several hundreds come in annually. H. P. Lie reviews leprosy in Norway, and has constructed an interesting graph showing a progressive decline in its incidence since 1856. Leprosy on the Gold Coast is dealt with by M. B. D. Dixey; in many parts there appears to be an utter indifference to the disease, which is regarded as resulting from some malign supernatural influence. In over 80 per cent. of the leper colony the disease is of the anæsthetic type. Treatment consists in injections of alepol, the external application of trichloroacetic acid, and the use of potassium iodide. Although the number discharged as bacteriologically negative has proved small, many cases are greatly improved, and the course of the disease is often arrested. M. Wardmann and E. Landemann conclude that alepol is superior to sodium gynocardate, and N. Pavloff advocates the use of 5 per cent. solution of chromic acid for ulcerative lesions of the mouth and nose. Tetrodotoxin, "prepared from the poisonous extract of the globe fish," is said to benefit some cases of leprosy neuritis, and I. Kerr reports that the sedimentation test is proving of value in controlling the duration of leprosy treatment.

ATURDAY, MAY 3, 1930.

IN HEALTH INSURANCE.

the Government actuary on the blement experience of a group of s, summarised on pp. 981-3, has ing situation. The figures published growth in the number of persons benefit, the increase being most e claims of short duration. As a probable that the funds of many ow a deficit at the quinquennial y completed; not only may there of which to pay additional benefits sent rate of benefits may have to be ingsley Wood in the House of sday emphasised the gravity of the Mr. GREENWOOD proposed to meet field of inquiry and submitting the alitative council of approved societies. causes of this disquieting change National Health Insurance? That ibuted to any one factor is certain; rigns the whole field of insurance ust be reviewed. In the first place network of the Insurance Act may on. Based as it was on the sickness r Unity of Oddfellows for the years perience may not be applicable rsal system as the present. The great industrial concerns with a stration widely different from that y societies may account for some on. Through them many wholly a, would have been refused under a, have been State-insured. Sir assumes that since National Health tied compulsorily to those who were d July 15th, 1912, or who entered d the insured population at the d persons who were already disabled; p, that many bad lives and many ly included at the outset because, t, bility, they were really in employ- r another. It will be remembered, administered by the Post Office, til with the cases refused by the th but so few were in fact refused istributors were recruited mainly d not troubled to apply to any n. Secondly, it is all too evident ties are not in close enough touch rship. There is room for closer i societies, as well as for improve- vitation and in their insistence on g the conduct of members. In the of the *National Insurance Gazette* es are urged to "do something A person who gets a week's sick roved society to which he is not sympathy. He needs checking. s punishment." This is the first it admitted that approved societies power to control their members. do well to turn their attention to

the system of payment through the medium of agents. In their anxiety to keep in favour with insured persons these local canvassers interpret the rights of the members in a way that must lead to inordinate demands. Coercive pressure put on insurance practitioners is largely due to the advice of these agents, who leave to the medical practitioner the task of explaining the conditions under which sickness claims can be accepted. The ugly rôle of detecting the malingering devolves entirely on him.

In determining the growth of sickness claims, by far the largest factor is this attitude of the insured persons, which has undergone a change for the worse in the last few years. It is no exaggeration to say that they are out to get all they can in the way of benefits. The atmosphere has changed and many expect "assistance" in one form or another. Sir ALFRED WATSON shows that there are numbers of insured persons who, finding themselves out of unemployment benefit, apply for sickness benefit, and after running through both of these apply again for full sickness benefit, immediately on completion of the waiting period which must elapse before they are entitled to it. Are these people incapable of work within the meaning of the Act? Interpretation of this phrase is not easy and standards must vary. Many insured persons have a low threshold of health; when in full work they are below par, and in comparison with the healthy some degree of incapacity can always be found. But sickness claims cannot be based on vital statistics, and it would be impossible to restrict sickness benefit to those who have definite diseases. The industrial depression through which the country is passing must have its effect in lowering the vitality of the workers; bad housing and environment contribute their quota. Difficult as the practitioner's duty already is to decide which of his patients are legally entitled to sickness benefit and the necessary certificates, it is made ten times more difficult by the threatening attitude of insured persons whose claims are withstood. When at the request of the approved societies the regulation governing change of doctor was altered, so that insured persons could select another practitioner at once without any consent being required, a powerful weapon was put into the hands of the insured. The practitioner who takes a firm stand finds that he loses the insured person by transfer to another practitioner. The panel practitioner, although primarily a doctor, has become largely responsible for the correct administration of sickness benefit. He is now called upon, as Dr. G. L. McCULLOCH very ably points out,¹ for a high standard of judicial ability in making decisions. And when his patient leaves him the reason for transfer is more often connected with certification than with treatment. The Government has now stated its intention to reconsider the interval during which the patient can change his panel doctor.

Insurance practitioners have a right to expect more support from approved societies in their difficult task. If the Act is to achieve its object the growth in sickness claims must be thoroughly investigated. The immediate problem is to examine the claims of short duration. The waiting period of three days was intended to provide the necessary delay in certain cases in order to see whether actual incapacity developed. Examination of these cases when the first certificates are given will determine whether a reasonable standard in deciding incapacity is being applied. This is essential, for if the present volume

¹ Brit. Med. Jour., April 26th, Suppl., p. 193.

of sickness benefit continues unabated the proper development of the insurance scheme will be arrested. Insurance practitioners as a body can be trusted to coöperate in applying any remedy which can be found to eliminate the so-called "improper" claims. This will involve the maintenance of an agreed standard in judging of incapacity and the resistance to all and every urge to lower that standard. Each member of the insurance service should be able to count on the loyal backing of his colleagues and on their refusal to take advantage of him by readily accepting a disgruntled insured patient.

SURGICAL DEATHS.

THE human body frequently reacts to the strain of operative procedures in an incalculable way, so that every surgical act partakes of the nature of an experiment, and thus may differ in essentials from the performances of the chemist, engineer, or physicist, where the strengths of materials, their behaviour under stress, and their reaction to combinations of circumstances, may often be accurately estimated beforehand. Deaths are liable to occur after operations where the outlook has appeared favourable, and the reasons for these fatalities are frequently difficult to find. Yet it is literally of vital importance to assign such deaths to the right cause in order as far as possible to prevent reiteration of the tragedy, while it is due to the patient to have the real risk of any proposed operation put before him, and here is a place where the necessary information defaults. What the actual hazard is, taking into consideration a large range of procedures carried out by different operators in many clinics, can scarcely be discovered from surgical literature. Mortality figures of the most expert surgeons for such an operation as prostatectomy are quoted by textbooks and sometimes by operators; but both surgeon and author should know well enough that the figures do not represent the true mortality of the operation, as carried out by a surgeon of average ability who perhaps has not a clinic organised for this special branch of work. And, as in this valuable piece of surgical interference, so in many other procedures, the influences alike of individual skill and of proper environment and opportunities must be taken into account.

An article in the current number of the *Bulletin of the American College of Surgeons*, entitled the *Accrediting of Surgical Deaths*, presents the situation in a clear and striking fashion, while advocating a standard method of estimating the mortality of operations which could be used in many hospitals. An investigation carried out in certain American hospitals revealed the fact that institutions differed very greatly in their classification of deaths after operation; on the one hand in some centres every death after an operation was put to the account of surgical procedure, while, at the other extreme, there were hospitals where no fatality was deemed due to surgery unless some gross accident of technique during the actual operation itself was shown to have occurred. When a patient dies from a pulmonary embolism or cardiac collapse or pneumonia during convalescence, the operating surgeon is inclined to disassociate himself from the occurrence, but can be exculpated from the position of causal agent when the fatal complications would not have occurred had there been no surgical intervention? Yet such deaths are due not to defects in surgical skill but to gaps in our knowledge. The surgeon, though guiltless

of negligence—for he has applied to the problem of the patient's disease what knowledge is available—cannot evade responsibility for the fatal outcome. Nor should the surgeon desire to do so, for any other attitude, while lulling him into complacency, would stifle research as to the causation of these unfortunate results. To gain a true perception of what is the mortality after surgical operations, speaking alike generally or with particular procedures in mind, a decision should be attempted as to what deaths are to be accredited to surgery; and the first step to such a decision will be to obtain some uniformity in the records of different hospitals, when a comparison of reports should give a truer picture of operative risks than we have yet been able to envisage.

Dr. E. L. HUNT, the writer of the paper in the *Bulletin* referred to above, outlines a system by which some such collated information might be made available. The proposed records would comprise a preoperative diagnosis; a preoperative estimation of the surgical risk—including the method of evaluation employed; evidence obtained at operation and post-operative developments; a secondary evaluation of the condition of patient, when the primary appraisal has been proved to be wrong; and autopsy findings. The difficulties of the system are evident, for it would reveal defects in the practice of certain hospitals and indeed of certain operators; these form essentials preliminary to progress and the betterment of results. The final assessments would have to be made by some other persons than the operators. If the system were carried out in a clear, impersonal, and scientific manner, the surgeon should not feel that his personal integrity was assailed, and indeed should welcome such scrutiny of his work; but not all men take up this brave attitude under criticism, and while hasty or incompetent surgery would be revealed at its proper value there would be often room for the argument that haste had been employed in the interests of the patient, and had given rise to the appearance of incompetency. The method is primarily directed to the discovery of defects, for only after technical errors are exposed to the light of day can remedial measures be set in motion. Accepted in the right spirit there might result a general improvement in the standard of work done under the influence of greater surgical wisdom. A perception of operative risks in the hands of the surgeon of average ability would be revealed, whilst the assessment of individual surgical skill would be facilitated. No system ever devised can be without its drawbacks, and this is no exception, for there lurks the possible danger that surgical enterprise and research might suffer a check, when an intensive inspection of results was known to follow operative work. Partial gastrectomy for gastric ulcer, compared with gastro-enterostomy upon its introduction, was accompanied by a high mortality, yet it has proved in the end to be much more effective and scarcely at all more dangerous. Thyroidectomy for Graves's disease has passed through a stage of disheartening mortality to one where the risk is often measurably smaller than that of leaving the unfortunate patient to his fate. In both cases enterprise was ill rewarded at the outset. Will the surgeon whose reputation is assessed by the working of any such scheme be anxious to tread unknown fields? Safeguards would have to be devised to protect the legitimate investigator of new surgical methods. But if this were effectively brought about, it is difficult to see any objection to the institution of such a uniform investigation of deaths following operations as our American colleague suggests.

A NATIONAL MEDICAL SERVICE.

As an appendix to the annual report of the Council for the year 1929-30, the British Medical Association has issued proposals for "A General Medical Service for the Nation," and these were printed in the *British Medical Journal* of April 26th. They are fundamental. The service postulated is complete, and is considered under the heading of prevention and treatment. The professional position of the family doctor, the consultant, and the specialist being analysed, the foundation of any efficient system is declared to be the family doctor; and, accordingly, it is stated as implicit in any sound scheme for a national medical service that every individual in the community must be in a definite relation with a general practitioner. This is the existing position as far as the 15,000,000 of insured persons are in question, and the way in which panel practice can be extended to include dependents is laid down, though it is nowhere, apparently, stated what the exact range of population is for whom the benefits of the scheme are intended; granted that a contributory plan for securing medical service is better for some, is it to be assumed that it is best for all? Where, how, and for whom institutional treatment should be provided forms an important section of the document, and here the rôles of the voluntary and Council hospital—this is the name suggested for the transformed poor-law institution—are defined, and the difficulties in adjusting their common claims upon the assistance of their staffs are mentioned as matters requiring further attention. The creation of "Home Hospitals" is advocated, the institutions, whether separate units or annexes to existing hospitals, being for the use of those persons, not fit subjects for free or practically free treatment, who are still unable to pay the charges of private establishments. In the "Home Hospitals" the coöperation of general practitioners in institutional work would receive full play.

It is of great value to the country that the broad views of the British Medical Association upon the problems of national health should receive popular declaration. Close attention on the part of the Association has interpreted the messages of numerous reports from public bodies, of many schemes for medical benefit on special lines, and of many experiences that institutions of all sorts could relate. And the proposals of the Association, in piecing all this together, have been now submitted to the public as a coherent and inclusive scheme of medical service based on simple concrete principles. More is not attempted, while the fullest criticism of what has been done is implied by the comparison of the scheme to a plan submitted by an architect to a householder, who may decide that the specifications for construction, for extension, or for improvement so nearly meet what is wanted that the money must be found, or, on the other hand, may find the cost too high, and either decline to proceed or suggest modifications of a more modest sort. For the scope of the Association's proposals is enormous, being no less than to ensure that "every kind of service which may be necessary for the prevention and cure of disease and for the promotion of full mental and physical efficiency . . . should be at the disposal of every member of the community." In respect of prevention, the coöperation of the public is insisted upon; the duty of the individual to provide a healthy environment in his home and so to live as to promote the health of himself and family being the first step. The next is

the right use of the family doctor, who, by educating the individual and the family in the course of his curative and advisory work in the home and in his consulting room, can confirm his patients in their good conduct. Schools, by the education of the children in matters of health, and the public health authorities and voluntary agencies by the dissemination of information and counsel, should enable the public to appreciate the aims of organised sanitation, and stimulate them to play a helpful part, as occasion arises. The proposals of the Association under the head of prevention are here based upon the reiterated publications of the Ministry of Health and the emphatic essays of Sir GEORGE NEWMAN, but under the head of treatment the proposals have been inspired, it may be guessed, by some apprehension that the bureau may come to be unduly predominant. The claim that every individual should have a call upon a family doctor is a direct warning to the public that only by the observer who is in intimate and domestic touch with the sick can any certainty be obtained as to many of the circumstances of an illness. With the general practitioner becoming yearly, almost daily, better equipped, it seems curious that his position should require so much insisting upon, and yet it has been observed that many of the developments not only in public health but in therapeutics generally have been at the expense of the earning powers of the general practitioner. It will be remembered that last year the Council of the B.M.A. reported on the encroachment upon the sphere of private practice through the activities of local authorities and voluntary agencies, and the proposals of the Association at this place form, again, a recognition that the family doctor must be the foundation of any complete and efficient medical service. His life work is the sub-structure on which all forms of medical service can be built, and it is a proof of the partial nature of the public comprehension of scientific medicine that the general practitioner should find limits being set to his opportunities when he has never been better able to take advantage of them and develop them. That the public should turn to him not only in his personal capacity, but as a medium for obtaining the best advice from consultants and specialists, would seem obvious. Auxiliary forms of diagnosis and treatment should be available for all, but the public can only obtain these with any safety through the agency of the family doctor.

Those who find the proposals of the British Medical Association to be merely voicing oft stated and generally accepted sentiments may be reminded that the scheme of the Association is being laid before the public, and not before doctors only. We make no attempt to give in any sense a full résumé of this important document; it is a notable example of brevity when the range of subjects is regarded for which some 15 pages have been found sufficient, and any attempt at ordered curtailment would eventuate in little but a meaningless index of contents. The propounders of the scheme believe that, if put into operation, it would lead to complete coördination of the whole medical service for the community, while it will be gathered that the central figure in the coördination is the general practitioner. It is shown how he can be brought into relation with every institution and service in his area, could relegate his patients for treatment in accordance with their needs to places whose merits he could evaluate, while he would be in touch with the medical officers for school purposes and with organisations for maternity and child welfare, instead of being not infrequently

without the advantages of such contacts. Further, while hospitals are to take their proper place in general medical organisation, much of the time and money wasted in out-patients departments would be saved through the general practitioner's efforts, while he in his turn, especially through the Home Hospitals, would be able to turn institutional experience to the advantage of his patients and himself. The legislation required for such ends would take the form mainly of amendments to the National Health Insurance Acts, and is of the sort that can be readily justified to voters, but the financial side of the scheme is less promising. This matter is not closely dealt with in the proposals, as it is realised that before they can become practical politics their financial aspects must receive expert attention.

Annotations.

"No quid nmls."

IN MEMORY OF HARVEY.

LAST year, during the celebrations by the Royal College of Physicians of London of the tercentenary of the publication of *De Motu Cordis*, Sir John Rose Bradford published an appeal to the medical profession, intended also for the information of the public, in respect of the condition of the tower of Hempstead Church. William Harvey was buried in this church, and the tower collapsed some 50 years ago and has never been replaced. A strong committee was formed last year having for its object the raising of sufficient money to re-erect the tower of Hempstead Church as a memorial to Harvey. The sum of £5700 is estimated to be necessary for the work projected, of which £1500—and probably a little more—have been received, leaving the balance of £4000 to be obtained through the generosity of subscribers, individual or corporate. The appeal was primarily to the medical profession and has resulted so far in this creditable response, to which the great medical institutions have contributed as well as Caius College, Cambridge, where Harvey received his education, and Merton College, Oxford, where later he was warden. Harvey is among the greatest of Englishmen, and the memorial thus suggested is out of all comparison small when set beside his achievement, for all mankind has benefited to an incalculable degree from work which provided a new and true foundation for physiology. So that the small sum needed to erect a material monument to his fame ought to be forthcoming promptly. Donations should be made payable to the Harvey Memorial Fund and sent to the hon. treasurer, Mr. A. W. Ruggles-Brise, Spain's Hall, Braintree, or to Dr. Arnold Stott, 58, Harley-street, W.1, joint hon. secretary with the vicar of Hempstead.

RADIUM IN THE TREATMENT OF INTRA-OCULAR TUMOURS.

In the April number of the *British Journal of Ophthalmology* we read of what we take to be the first case of sarcoma of the choroid cured by the insertion of radon seeds. The patient was a man aged 65 with a large typical sarcoma of the choroid, who was first seen at Moorfields by Mr. W. S. Duke-Elder. As the unaffected eye was blind the patient not unnaturally refused to have his only seeing eye excised—hitherto the only treatment found effective in preventing the spread or dissemination of a malignant tumour of the retina or choroid. The case was, therefore, suitable for experimental treatment by radium, and was transferred to the care of Mr. Foster Moore at St. Bartholomew's Hospital for the purpose.

At first a radon seed of 1 millicurie strength, filtered through 0.5 mm. of platinum, was introduced through a minute incision in the sclera, and left embedded in the tumour for 14 days, after which it was removed by the same route through which it had entered. No very obvious change in the condition of the eye followed, and about four months later a second seed was inserted, this time of a strength of 5 millicuries, with the same filter as before. Less than three months afterwards it was clear to all observers that the growth was shrinking. Five months later still (February, 1930) Mr. Duke-Elder reported that the mass had shrunk to about one-quarter of its size when he had last seen it a year ago. The residue, he thinks, is merely fibrous tissue. Mr. Foster Moore's comment on the case is that the point of paramount importance is the fear of dissemination. When the growth begins to shrink are we justified in assuming that the danger of dissemination has ceased? It seems unlikely, he says, that actively growing cells will be thrown off from a tumour which has begun to regress. If so, the eye no longer remains a menace to the patient, and he is as much protected against dissemination (no more and no less) as if he had had it removed. If, he goes on, we are prepared to accept this view, it seems reasonable to treat any case of accessible intra-ocular sarcoma by the foregoing means when the growth has not as yet seriously spoiled the eye, and in the rare cases when the growth occurs in an only eye, or the only useful eye, it appears to be the proper treatment.

Mr. Foster Moore has adopted the same treatment for glioma, in the case of a boy of 4 years old, one of whose eyes had already been excised two years previously for the same condition. In this case the strength of the radon seed was 3 millicuries, and it was left in the tumour for ten days. As the date of this insertion was only last November, it is too soon to be certain of a complete cure, but the growth had very largely disappeared when he reported¹ it to the Royal Society of Medicine.

EARLY MORNING IN HOSPITAL.

THE rearrangement of the ward work at the Middlesex Hospital in order to avoid disturbing patients before 7 A.M. has stimulated other authorities to consider whether these adjustments are worth making. The Central Bureau of Hospital Information, established under the auspices of the British Hospitals Association and the Joint Council of the Order of St. John and the British Red Cross Society, has received replies from 63 provincial hospitals to a questionnaire on the subject. The accommodation in these hospitals varies from under 100 to over 1000 in-patients, and the wards contain from 13 to 40 beds; each ward needs a day staff of from 3 to 11 and a night staff which in no hospital exceeds two, supplemented in eight hospitals by "runners" to take urgent messages. The information provided includes also the times at which day and night staffs come on and off duty, at which work commences in the wards, and at which breakfast is served to patients and nurses. The hour at which wards are ready for visiting by the resident medical staff is also stated and the hour of attendance by the honorary medical staff, with the earliest operation hour in routine work. The Bureau also asked each hospital to estimate the additional staff required to avoid disturbance of patients before 7 A.M., and to give an opinion on the wisdom of such a change. An examination of the figures supplied shows that the day nurses mostly come on duty at 7 A.M. and the night nurses go off duty between 8 and 8.30 A.M., overlapping with the day staff in the morning for one hour to an hour and a half. In three hospitals (Nos. 9, 14, and 63) there is no overlapping in the morning. In 45 hospitals work begins in the wards before 6 A.M., and in 18 at 6 A.M. or later. The

¹ Proc. of Roy. Soc. Med., February, 1930, p. 475.

interval between the beginning of work and breakfast varies from 0 to 24 hours, the majority of hospitals allowing from 30 to 60 minutes. The interval between the beginning of work in a ward and the morning visits of the honorary medical staff varies from 3 to 44 hours. With regard to the extra staff required for a postponement of morning activities, the various opinions expressed reflect the difficulty involved in estimating the effect on staff whenever a load factor is increased sharply and for a limited period. Some hospitals protest that the present staff might have to be doubled; others confess that the increase would be difficult to estimate; six announce that no additional staff would be required. The comments are interesting. Roughly half the hospitals consulted point out various difficulties and express doubts whether a later time for opening the wards is practicable or even desirable. About one-third of the hospitals praise the scheme and have either adopted it or are considering its adoption. About one-sixth of the hospitals believe that later rousing is unnecessary or inadvisable, some giving no reason and others saying that patients are used to early rising, may be awake and hungry, and are anyhow likely to need attention before 7 A.M. Moreover—and this is the most crucial argument against a change of organisation involving more staff—the patients in wards which close down, say, at 8 P.M. and open at 6 A.M., get the opportunity for ten hours of undisturbed sleep. No information was apparently asked for—at any rate none is given—about the hour when lights are put out in the various hospitals. Hospital No. 33 suggests that so long as patients get the proper amount of sleep the actual hour of waking is not of great importance. Most people will agree with this dictum, with the important reservation that patients recently admitted to hospital or at home after discharge are not likely to get a good night's sleep if the day's routine at hospital is in sharp contrast with that of home life. Few adults habitually go to bed at 8 P.M., and during the first two hours of the hospital night many patients remain restlessly awake, especially in the summer. Probably the best solution for those hospitals whose wards open at 6 A.M. would be one which could be adopted with no alteration except a psychological adjustment and one to which the Daylight Saving Bill has already accustomed us. Assuming that a ward which is now ready for the doctor at 9 A.M. was allowed to remain closed till 10 A.M., the whole hospital routine could be shifted forward by one hour and no one, except perhaps the house surgeons and students, would suffer. The patient's day would be more like his normal one, the nurses' evening off-duty times would extend to a more convenient hour, and the change would cost nothing.

TESTICULAR GRAFTS.

THE controversy about the experiments of Voronoff has been based on very few facts, and it has been hard to get independent and reliable testimony. The results obtained by Dr. E. Schleyer¹ are, therefore, of interest. He has operated on nine patients, eight of whom ranged in age from 49 to 70, the exception being a eunuchoid of 37, who insisted on undergoing the operation against advice, and who did not benefit. In five of the eight Schleyer claims to have produced appreciable rejuvenation lasting for one to two years. The method was Voronoff's own—namely, transplantation of two slips of ape's testicle into the tunica vaginalis on each side. Schleyer never performed a test excision of the graft in any of these cases, but relied on the somewhat crude method of palpation to inform him of its fate. After nine months the slips were no longer palpable, although the effect continued. He does not agree with Voronoff that the grafts become vascularised and incorporated with the testicle of the host. The effect on the host

is, he thinks, due to two or three causes. The hormones produced by the graft or set free when it is absorbed stimulate the testicle to a greater hormone production, and he thinks it probable that the protein substances of the graft stimulate the other glands of internal secretion. The operation can be repeated. Success, he thinks, depends upon a correct choice of patient and on early treatment. There seems no reason to doubt that under certain circumstances testicular grafts will mitigate or remove for a time some of the symptoms of age, but it seems to be fairly well established that Voronoff's method is at best only an administration of foreign testicular substance, and not in any sense a transplantation of a living organism.

HIGH PROTEIN DIETS AND RENAL INJURY.

CLINICAL experience has in the past led observers to regard large amounts of muscle protein as distinctly inadvisable for people suffering from renal diseases, and it has been thought that excessive consumption of meat may be capable of actually provoking renal lesions in man. A great many experiments have been done on animals in recent years to determine precisely the histological and functional effects of consuming abnormally high proportions of protein. The results have been conflicting, for, as might be expected, different species of animals respond to such diets in different ways, and varying renal responses follow the giving of different kinds of protein. Controlled experiments with man himself as the test animal have not been frequent. It may be remembered that a little while ago the Arctic explorer Stefansson and his colleague Andersen subjected themselves for a year to an exclusively meat diet, and that this was found to have had no demonstrably injurious effects on their kidneys.¹ It was pointed out at the time that their actual consumption of protein was not especially high, so that the experiment did not settle the question as to the effect on man's kidneys of excessive amounts of meat protein. Prof. Newburgh,² who has been engaged for some years in investigating the toxic effects of high protein diets on animals, has recently reported, in conjunction with some of his colleagues, an experiment on similar lines carried out with a man. For six months their subject, a man of 32 apparently in perfect health, lived on a diet containing a daily allowance of 337 g. of protein. The bulk of his food consisted of fresh beefsteak, veal, and beef liver. The meat was supplemented by green vegetables, butter, and citrus fruits. No subjective disturbances of any kind were noted during the six months and the subject's blood pressure remained unaltered throughout the period. Six weeks after the beginning of the test a slight cloud of albumin was noticed in the urine, and the amount steadily increased till at the end of the sixth month 2 to 4 mg. was being excreted each hour. Ten days after the completion of the experiment and the resumption of a normal diet the albumin had completely disappeared. Perhaps of more significance than the slight degree of albuminuria provoked by the diet was the appearance of increasing numbers of casts in the urine. After two months there was an average excretion of about 1000 casts per hour, and at the end of six months the number was approximately doubled. In the early stages of the experiment the casts were hyaline, later more and more of them were of the granular variety, and towards the end cellular casts were met with. They had completely disappeared from the urine ten days after a normal diet had been resumed. The evidence collected in this single experiment certainly lends support to the view that excessive amounts of meat protein can damage the kidneys in man. Whether considerably smaller amounts taken for a much longer time might have a similar effect cannot be presumed without experimental proof; there is certainly at present no convincing evidence

¹ See THE LANCET, 1929, II., 238.

in favour of the view that the amount of meat protein ordinarily consumed by the Western races of mankind can itself initiate renal disease.

A NEW PRINCIPLE FOR AIDS TO HEARING.

THE act of hearing is accomplished by the vibration of end-organs in the cochlea induced by sound-waves which penetrate to the internal ear, and our present methods of assisting hearing involve various forms of apparatus designed to increase the energy of these sound-waves and to conduct them to the cochlea through the middle ear or through the cranial bones. In the telephone, and in electric hearing aids, the sound-waves of speech cause vibrations in a microphone; these vibrations produce modulations of an electric current which, in turn, cause identical vibrations in the microphone of the receiver, and thus reconvert the electric current into waves of sound. It has occurred to Prof. S. Jellinek and T. Scheiber, of Vienna, that the perception of hearing might be accomplished by conducting the modulated electric current directly to the cochlea without first re-converting it into sound-waves. In a preliminary communication¹ they say that they are now able to conduct such a current to the ear and by this means to hear and to differentiate speech, music, and other sounds, and that this hearing is unaffected by plugging the auditory canal. They give no description of the apparatus by which their results have been obtained, and a further communication will be awaited with interest, for the method may prove to be valuable if clear perception of sound can be produced by it in a convenient and practical manner.

RICKETS IN EGYPT.

In European countries it is generally supposed that rickets is a disease of northern climates where sunlight is deficient. Tropical or sub-tropical countries are believed to be happily free from rickets, as witness the statement of one authority that "in Egypt, India, and China, where infants are brought up in the open air, and where they are bathed in daily sunshine from their birth onwards, no errors in food will produce the disease." How far this statement differs from the truth was pointed out by Dr. I. Shawki, in an address to the International Congress of Medicine and Hygiene, which has now been printed.² Of 500 children between the ages of six months and two years, who attended the out-patient department of the Kasr-el-Eine Hospital, 45 per cent. showed bony manifestations of rickets and among 100 apparently healthy children, 23 per cent. showed evidence of rickets on radiographic examination. The causes of these high figures, Dr. Shawki pointed out, cannot be those usually assigned to the production of rickets—namely, absence of sunshine and artificial feeding. Egyptian sunshine fails for perhaps a fortnight in the year, and breast-feeding of infants is the rule, not the exception. There is some evidence that the ultra-violet rays are less powerful in flat low-lying countries, but even so they are probably considerably stronger in Egypt than in countries north of the Mediterranean, though dust may absorb a certain amount of the rays. There is, however, another reason, and one which Dr. Shawki did not mention. The fact is that the Egyptian infant is scarcely ever exposed to the sun. If the poorer class Egyptian mother is asked to undress her child she will draw up two or three thick outer garments and show a cotton or wool shirt which is bound down to the baby by a thick binder of some felt-like material, five inches wide and a yard or more in length. This is rolled round and round the child even during the hottest weather. When fully dressed the child is carried over the maternal shoulder wrapped in the folds of her black draperies.

If he sees the sun at all he is fortunate, and as to playing in the open air or bathing in sunshine, his mother would consider such a suggestion madness. Dr. Shawki mentioned prolonged lactation as a common cause of rickets in Egypt; a child is usually breast-fed until he is two years old, or a girl for 18 months, as being less important. If it is remembered that the diet of the poor-class Egyptian mother is scanty, and poor in vitamins, and that other food is not considered to be necessary while a child is taking the breast, the ætiology of Egyptian rickets becomes less obscure.

Dr. Shawki made a third suggestion: frequent gastro-intestinal disturbances may interfere with the absorption of calcium and phosphorus and increase the tendency to rickets. Gastro-enteritis from various causes is, of course, extremely prevalent among Egyptian infants, and is responsible for a large proportion of the death-rate.

PRE-SCHOOL CARE.

THE school medical report from Eccles throws some light on the needs of children aged 2-5 years. It is often stated that from a quarter to a third of school entrants are physically so defective as to be scarcely fit to receive education. Last year Dr. J. E. Spence found that the proportion in Eccles was 23 per cent.; of these, avoiding all exaggeration, in one-fifth the state was serious, in the majority being more or less transitory. Squint he does not include among the serious defects, although its preventive treatment is urgent, a fact of which Dr. Spence shows he is fully aware in his report. The point to which we would draw attention here is that a large proportion of the defects are preventable; Dr. Spence holds that nine-tenths of them could be obviated by improved nurture and environment in early childhood. How can healthy conditions of life, training in hygienic habits, medical care and treatment be brought to bear on the pre-school child? In their endeavour to answer this question the borough council of Eccles have merged the child welfare and school medical services so that children not yet of school age are supervised by health visitors, and have all the facilities of the school clinics open to them. To reduce the gap, they have encouraged the admission to school of children from 3 to 5 years, 44 per cent. of whom are now actually in attendance. But more is needed and is evidently desired. The number of younger children making use of the school clinics is as yet far too small; and the majority are still having no systematic medical care or hygienic education. The provision of nursery schools might help, but the experience in Eccles is that parents are for the most part unwilling for the 2-3 year-olds to attend school, and it is estimated that not more than 15 per cent. of them would do so, even if the provision was made. It is more necessary in the poorer and more crowded parts of a town, but on grounds of economical administration Dr. Spence would prefer to have nursery classes in existing schools, given the necessary extensions and alterations of the premises. His own observations may justly lead others to conclude that (1) the care of the pre-school child is worthy of close attention and vigorous action; (2) for the 2-3 year-olds the coöperative activities of health visitors and treatment clinics should be widely utilised; (3) for the 3-5 year-olds admission to the elementary school should be encouraged when home conditions are not good; (4) in the poorer areas, nursery classes should be held in connexion with existing schools, and where practicable nursery schools set up. Two further lines of attack not specifically mentioned in Dr. Spence's report may be suggested. (5) Parents should be advised to keep their children under the regular care of their own doctors; (6) the mothers of the next generation should be taught the principles of healthy upbringing. Ideally no doubt the widespread development of nursery schools is the way to deal with the problem.

THE NECESSITY OF A DEFENCE SOCIETY.

At the annual meeting of the London and Counties Medical Protection Society Sir John Rose Bradford pointed out the absolute necessity for the existence of "protection organisations," and we may draw attention to his words, though their message is so familiar, because, speaking from a long experience, he suggested that the volume of legal work which would have to be undertaken in the interests of medical practitioners was likely to increase in the future. That is to say that, while medical practitioners seem in increasing numbers to insure against the risk of legal actions, those actions are increasing at a similar or even faster rate. From the annual report of the L.C.M.P.S.—which is not happy in its drawn-out title—it can be gathered that the cases dealt with by the Society during the past year have fallen mainly under the heading of charges brought against members of negligence or unskilfulness. Further, the liability to these charges was increased by absence of precaution on the part of the medical practitioner when, as was very generally the case, an accusation of malpraxis followed treatment for fracture. The opportunities for making these charges have multiplied, obviously in proportion to the increased opportunities for useful surgical interference which modern surgery furnishes. The public are fully aware, as is right, that radiology can often give critical information for the guidance of the surgeon in diagnosing a bone injury, and in repeated cases, where accusations of negligence have been made, had the medical practitioner insisted upon the patient having an X ray examination the charge would never have been brought. But where a dissatisfied patient consults a radiologist some time after the injury, while the doctor has not called the radiologist to his assistance at the time of the injury, the defence against a charge of negligence becomes difficult. The fact that the charge is often not a sincere one, but represents only a manoeuvre to avoid payment of a legitimate bill, is beside the point—this is a hard thing to prove, as the money may be withheld out of a genuine disappointment with the treatment, while, whatever the patient's mainspring of action may be, the trouble arising will be the same. Hence in all injuries where it is possible that fractures or dislocations, or both, may have occurred, medical practitioners should secure the support of an X ray examination, and should try to persuade patients of the value of the procedure if they are unwilling to incur the expense. These warning words have been written in *THE LANCET* before, as they no doubt have been included in the annual reports of various defence associations for many years, but the counsel should be repeated, because this professional risk tends to become more common; and every successful claim of this sort—successful generally because the practitioner has not protected himself in advance—stimulates a certain kind of patient to make a charge of negligence as a way of getting out of paying his bill.

PSITTACOSIS AND THE IMPORTATION OF PARROTS.

THE Ministry of Health and the Department of Health for Scotland have issued orders prohibiting the importation into this country of "all birds of the parrot species" after May 19th. This step is taken for the protection of the public against psittacosis, and the regulations will not apply to parrots required for medical or veterinary research or those consigned to the zoological societies or to persons specially authorised. In the House of Commons on April 16th Miss Susan Lawrence stated that "information has been received in the Ministry of Health of 80 cases of illness which commenced during the present year and in which the patients had been associated with sick parrots." Thirteen of these cases proved fatal, and in nine of them psittacosis appeared on the death certificate as the cause of

death. In stopping the importation of parrots Great Britain is following the example of most of the other countries in which the disease has appeared. A review of the subject just published by the secretariat of the League of Nations¹ describes the incidence in these countries and goes on to discuss the ætiology at length. Bacteriologists in France, Germany, and the United States have now confirmed the observations which Bedson, Western, and Levy Simpson reported in our issues of Feb. 1st and 15th, and it is generally agreed that the disease is caused by a filtrable virus. But the League of Nations reviewer is loth to abandon previous ideas, and ingeniously reconciles two schools of thought by suggesting that the virus may be a filtrable phase of a typhoid or food-poisoning organism. Indeed he goes so far as to say that it may "be admitted, until proof is furnished to the contrary, that, bacteriologically, psittacosis is caused by a filtrable virus belonging to the salmonellos group."

HULL AND MUNICIPAL RADIUM.

THE Kingston-upon-Hull Corporation Bill, which is awaiting a third reading, contains a novel clause (42) dealing with radium supply. As the Local Legislation Committee has approved the clause in an amended form Parliament will presumably accept it. For several years, thanks to the activity of a former medical officer of health, the municipality of Hull has been building up a supply of radium which now amounts, it is understood, to 1034 milligrammes. The Corporation could, of course, utilise this valuable possession in the exercise of its poor-law functions, but it desired to make the radium available to the fullest extent. It therefore seized the opportunity arising out of the promotion of a local Bill on more general matters, and asked for special powers to "purchase or hire or enter into any agreement or arrangement for the use of radium, and supply it to any medical practitioner with or without any charge therefor." This new provision was tacked on to a clause of a not unfamiliar type under which the municipality was to be empowered to supply medical practitioners with medicines, appliances, and requisites for the care and surgical treatment of sick persons. The Local Legislation Committee inserted the following proviso to this clause as to the provision of medicine, &c., generally:—

"Provided that the medicines, appliances, and requisites to be supplied under this section shall include only those in respect of which, when supplied by a duly qualified medical practitioner under the National Health Insurance Act, 1924, payment is made on the basis of the drug tariff for the time being in force in the city."

As to the provision of radium the Committee has converted the proposed subclause into a new clause (42A) more strictly framed. The new clause authorises the Corporation not to deal directly with the purchase, hire, &c., of radium, but to "make reasonable subscriptions or donations to any trustees or other body constituted for the purpose of holding, supplying or administering radium, and, on making any subscription or donation under this section the Corporation may impose such terms and conditions relative to the supply, administering or use of radium as they may think fit." The expenditure in this connexion is not to exceed a penny rate. The amended clause, which the Ministry of Health has presumably approved, seems wide enough for all practical purposes. The working of this bold experiment will be watched with interest.

THE STORY OF A SURGEON.¹

Sir John Bland-Sutton tells the story of his life—or rather the notes for such a story—with the kindness, simplicity, and learning which his writings, whether addressed to scientific or more popular

¹ Monthly Epidemiological Report, April 15th, p. 111.

² The Story of a Surgeon. By Sir John Bland-Sutton. London: McEuen and Co. 1930. Pp. 201, 12s. 6d.

audiences, have always exhibited. He describes his childhood with considerable detail, records his early interests in natural history, which were hereditary and which thrived in a fortunate environment, and in these early chapters he draws upon his memory for multifarious incidents which determined him to become a surgeon and which compelled him to remain a naturalist. Two closely written chapters are devoted to experiences as a prosector at the Zoo, and it is when recording these events that the author explains how often passages in his book must have lain dormant in his mind for years to recur with vividness during the process of writing. It is this spontaneous character of the reminiscences, whether concerned with hospital, official or private life, with strenuous work or holiday excursions, which alike accounts for their fascination and also for the fact that no very accurate time-chart has been kept in the record of the occurrences. Many reminiscences are included of the professional leaders with whom, in the wards of the Middlesex Hospital and elsewhere, the author was brought into contact, and they are all set down with great charity; those who studied medicine round about the late 'seventies will find much to interest them in the references to Sir James Paget, Hulke, Lister, Freeman of Bath, Douglas Powell, Sir William Flower, Greenhow, Lawson Tait, Sir Patrick Manson, and others, and we are glad to see that the work of Thomas Cooke, in the last of the private anatomy schools of London, receives a word of appreciation. Sir John is the most modest of authors, and in supplying an annotated list of his writings he leaves to others all estimate of their value. Few readers would gather from the notes which he makes on "Tumours, Innocent and Malignant," that this book, written nearly forty years ago, and the first in which tumours were classified in any logical manner, proved a revelation to students in the year of its publication, and revolutionised immediately much of the pathological teaching current at the time (1893). Consecutive editions appeared until the author decided to allow the manual to remain in the form in which it was issued in 1922 as evidence of the state of clinical knowledge in regard to tumours at that date. A preamble to the volume, furnished by Mr. Rudyard Kipling, takes the shape of an encouragement to produce the volume couched in mediæval English, and addressed to the "Knight and Chirurgeon in his work and heart of Middlesex."

THE ROSS INSTITUTE.

THE annual report of the Ross Institute for 1929 indicates the directions in which research is being pursued by the staff and by voluntary workers in the several departments. Dr. J. A. Shaw-Mackenzie, Dr. Jackson Clarke, and Dr. Tertius Clarke have worked in the department of tropical hygiene, which is under the direction of Sir William Simpson. In the department of tropical medicine and dermatology Sir Aldo Castellani, the director, has continued his researches on fungi and fungal diseases, and has investigated various types of colitis; Dr. Mackenzie Douglas has worked on the effect of the growth of intestinal bacteria on carbohydrates and allied substances. The report describes in some detail the active anti-malarial work carried out under the auspices of the Institute and its director-in-chief, Sir Ronald Ross.

The new Malaria Laboratory at the Institute is now complete and well equipped. Two planters' courses have been held there and doctors either from or proceeding to the tropics have used the laboratory to study both the entomological and practical sides of malaria control. The Industrial Anti-Malarial Advisory Committee of the Institute was inaugurated on July 13th, 1929, and the Committee has since met quarterly to consider problems relating to the economic control of the disease in tropical industries, and to promote and assist the anti-malarial work which is being done in different parts of the world.

The Committee has members who represent industries in India, Ceylon, Rhodesia, Malaya, Java, Borneo, and Sumatra, and the services of others representing industries in Africa and of British interests in South America are to be enlisted. A Malaria Expedition toured India in 1928-29. Sir Malcolm Watson comments on "the number of invitations extended to the expedition which showed the great interest now taken in the prevention of malaria, and a fuller realisation of the economic loss it causes to India." In some places anti-malarial work was started during the visit of the expedition; in others arrangements were made for further preliminary scientific work. Industrial companies which have already reaped benefits through approaching the problem by the close association of science and practical work are increasingly supporting the Institute.

The Anti-Malaria Co-operative Societies of Bengal were found to be doing valuable work, and satisfactory reports have been received from the iron ore mines belonging to the Tata Iron and Steel Company of the results of anti-malarial work carried out under Mr. Senior-White. Malaria control at Noamundi mine is apparently admirable. The initial efforts made during the last few years in Assam have proved according to this report that the control of malaria on tea estates in Assam is not only possible but also economically practicable.

In Northern Rhodesia, the directors of the Roan Antelope Copper Mines and the Rhodesian Selection Trust, invited the Institute to assist them in improving the sanitation of their copper properties and in eliminating malaria. Two expeditions have been sent out, the first consisting of Sir William Simpson, Dr. A. Dalzell, and Mr. C. R. Harrison. Sir William returned after four months, and submitted a full report on general sanitary measures and housing to the directors in London. Mr. Harrison stayed for six months to make a survey and start the control work, and Dr. Dalzell will remain in Northern Rhodesia on behalf of the Ross Institute, as special scientific officer to the companies, until permanent arrangements have been completed. Sir Malcolm Watson later visited Rhodesia to inspect the anti-malarial work in progress on the mines and to investigate certain aspects of the problem. Much importance is attached by the Institute to propaganda work with regard to malaria. A paper for laymen on the prevention of malaria, first published by Dr. Cuthbert Christy in 1917, has been brought up to date, and is being issued for free distribution to residents in the tropics in a water and insect proof cover. The distribution will be made through the various Chambers of Commerce and Associations connected with tropical industries throughout the Empire and should have useful results.

THE Minister of Health has decided to restore the Chairmanship of the Welsh Board of Health, and has appointed to the post Mr. John Rowland, a member of the Board and Deputy Controller of Insurance. The Board will henceforth consist of Mr. Rowland, Dr. Llewelyn-Williams, and Mr. Howell E. James.

BOSTON CITY HOSPITAL.—A report of this hospital at Boston, Massachusetts, has now been issued for 1928 and shows that the cost per patient per day was a little over 18s. while at the convalescent home it was, roughly, 14s. 8d. At the hospital proper each out-patient visit cost about 2s. 3d. Over £21,000 was received from paying patients. There were 23,576 in-patients and 291,557 out-patients. During the year an "afternoon medical out-patient clinic" was opened for the benefit of patients "whose problems require more than the average amount of personal attention the patients require from physicians." The clinic is open three afternoons weekly, and the work is undertaken by three physicians, one of them resident, and three or four fourth year medical students. A new residence for "house officers" has been built at a cost exceeding £71,000, containing a swimming pool, two squash rackets courts and lounge, a card room, a reading room, and sun rooms.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

LXX.

THE SIGNIFICANCE OF BLOOD GROUPS.

PART I.*

ALTHOUGH the first steps towards the identification of the blood groups were made by Landsteiner so far back as 1900, it is only during the last ten years that medical students have been expected to know something of their nature and constitution. The matter has been immensely complicated by the fact that the existence of certain differences in the blood of human beings, differences which enabled them to be classed into four groups, was discovered and reported independently in Europe by J. Jansky and in America by W. L. Moss. The European observations, which preceded the American ones by two years, were unfortunately reported in a continental journal little read outside the country of its publication, and as chance would have it the two discoverers used different numerals to identify their groups. Moss's terminology holds in this country; that of Jansky has been largely adopted in America and on the continent, and as a consequence it is always uncertain what group is meant when an author refers to Groups I. and IV. In the present article it is proposed to discard the numerical indications of the groups and to use terms indicating their actual constitution, so far as is known. This is made possible by the work of von Dungern and Hirschfeld, who in 1911 showed that the existence of the four blood groups could be explained by the assumption of two different agglutinins factors resident in the red cells and two agglutinins corresponding to them resident in the plasma or serum. The agglutinable factors of the red cells, or as they are now described the agglutinogens, they called A and B, the corresponding agglutinins they designated by the corresponding Greek letters α and β .

Table I. shows the structure of the four groups according to the scheme of von Dungern and Hirschfeld and their correspondence with the numerical designations of Jansky and Moss.

TABLE I.

Agglutininogen.	Agglutinin.	Group.		
			Jansky.	Moss.
A and B.	Neither.	A B.	IV.	I.
A only.	β only.	A.	II.	II.
B only.	α only.	B.	III.	III.
Neither.	α and β .	O.	I.	IV.

The constitution of the blood groups as described by von Dungern and Hirschfeld has been called into question from time to time. Up to two or three years ago attempts were made by various authors to demonstrate that the agglutination phenomena could not possibly be so simple as they appeared, and that actually other agglutinogens in addition to those described as A and B must exist, with corresponding agglutinins. Recent work has made it fairly clear that the apparent exceptions discovered by various workers were due to errors of technique, and it is now generally admitted that the hypothesis of von Dungern and Hirschfeld suffices to explain the known facts.

These workers gave good grounds for believing that the factors A and B act as dominants and are transmitted from parent to offspring according to Mendelian

laws. That this is true has since become abundantly evident; its importance is discussed below.

Blood Transfusion.

For some years after the demonstration of their existence the blood groups had no applications in clinical medicine. Their importance first became evident in connexion with the transfusion of blood; to instil the blood of a healthy subject into an anæmic patient appears to be an obviously desirable procedure and has enjoyed a varying vogue for some hundreds of years; it is only within the last half century, however, that surgical technique has made the operation really feasible, and it was not until the years immediately preceding the war that it enjoyed any widespread popularity. At that time blood transfusion was beginning to find its way into clinical medicine, but it was generally recognised that the procedure possessed the drawback that while in many instances the intravenous introduction of blood was beneficial, in other cases the results might be catastrophic. It was further realised that a blood which suited one patient admirably might be far from suitable to another. It was not until the war had made blood transfusion an almost daily occurrence that it was realised that it was only safe to introduce intravenously red cells which were not agglutinated by the serum of the recipient, otherwise the latter would become acutely ill, and perhaps die; if he survived he would develop hæmoglobinuria, become jaundiced, and in a few hours would be found to have lost all the infused blood.

Experience has now served to establish the general rule which must always guide the selection of donors for transfusion that a compatible blood is one the red cells of which can neither be agglutinated nor lysed by the plasma or serum of the recipient.

Reference to Table I. will show that given knowledge of their groups it is possible readily to ascertain beforehand whether or not the red cells of any proposed donor are capable of being agglutinated by the serum of any proposed recipient, in other words to determine compatibility. Thus the serum of an A B individual contains no agglutinins and can agglutinate no red cells; such an individual can receive blood from anyone—he is a "universal recipient." The blood of an A individual contains the agglutinin β ; he must not receive blood from groups A B or B. Similarly a B individual must not receive blood of constitution A or A B. Individuals of the O blood constitution, since their serum contains both agglutinins α and β can receive blood from none but members of their own group, but may give blood to anyone; they constitute the "universal donors" and are much in request for transfusion services, so much so that possession of the O blood constitution has a distinct financial value, particularly in America.

Determination of Group.

Reference to Table I. will make it clear that to determine the group of any given individual there are required red cells from the subject of the test and known sera of Groups A and B. If on mixing the red cells with the sera agglutination occurs with both the A and B sera the subject belongs to Group A B; if agglutination occurs with the A serum only to Group B; if with the B serum only to Group A, and if with neither to Group O.

Selection of Donors.

Since Group O consists of the so-called "universal donors" it would seem simple enough, given suitable samples of sera of Groups A and B, to discover donors suitable for transfusion purposes. It is not, however, quite so easy as appears, since the agglutinin titre of the serum of different persons varies considerably, and even in the same individual the titre is subject to variations from time to time. Unless the user has long experience of his grouping sera, he can never be sure of their titre, and may without knowing it be using a serum too weak to identify in all cases the corresponding agglutininogen. As a result of the

* Part II. will appear next week.

variations in agglutinin titre he runs the risk of identifying as O a blood really of the constitution A or B, or he may even be led to regard as A or B bloods which are actually of the constitution A.B. Thus blood of the constitution A or B may inadvertently be introduced into the circulation of a subject with sufficient α or β agglutinin in the serum to bring about agglutination or lysis of the red cells. The results of such an error are never beneficial and frequently disastrous.

Blood Matching.

There is only one safeguard against accidents of this sort, and that is direct matching of the bloods of the proposed donor and recipient. For this purpose are required a few drops of the serum of the proposed recipient and an emulsion of the red cells of the proposed donor. One drop of each of these is brought together on a slide; if neither agglutination nor lysis of the red cells occur the bloods are compatible.

In cases of urgency it is justifiable to use blood of a known or supposed donor of Group O without further testing, but where time allows matching should always precede transfusion. Most of the disasters reported in connexion with transfusion have occurred in cases in which compatibility was tested by grouping alone, without direct matching. I know of two cases in which, owing to weakness of agglutinin titre of the sera used, incompatible bloods were infused under the impression that they belonged to Group O. Actually in both cases they belonged to Group A.

There are good grounds for believing that death following incompatible transfusion is often due to blocking of the renal tubules by the hæmoglobin liberated from the lysed red cells. Precipitation of hæmoglobin from solution will only occur in an acid urine; when selection of donor is by group alone, without direct matching, it is advisable to attempt to render the urine alkaline. When the citrate method is used the infused citrate is usually sufficient to bring this about, but even so it is good practice to give alkalis by mouth; where citrate is not used this should always be done if there is the slightest possibility of incompatibility.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdrs. N. B. de M. Greenstreet and T. N. D'Arcy to be Surg. Comdrs.

Surg. Lt. J. V. Williams to be Surg. Lt.-Comdr.
The following appointments are notified: Surg. Comdr. T. N. D'Arcy to *Calypso*; Surg. Lt.-Comdr. D. H. Kernohan to *Norfolk*.

ROYAL ARMY MEDICAL CORPS.

Maj. J. H. Fletcher retires, receiving a gratuity, and is granted the rank of Lt.-Col.

ARMY RESERVE OF OFFICERS.

The undermentioned, having attained the age limit of liability to recall, cease to belong to the Res. of Off: Lt.-Cols. J. H. Brunskill and O. R. L. Ronayne.

TERRITORIAL ARMY.

Col. C. R. White, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

Lt.-Col. (Bt. Col.) O. B. F. Planck, from 18th (S. Midland) Divl. Train, R.A.S.O., to be Col.

Capt. A. A. Watson, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

Lt. T. Wallace to be Capt.
Lt. M. J. A. Pilot to be Lt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Col. H. Burrows, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

Maj. A. C. M. Savege from Active List to be Maj.

ROYAL AIR FORCE.

The short service commission of Flying Officer Abraham Henry Barzilay is antedated to Oct. 1st, 1929, and he ceases to be seconded to the Royal Southern Hospital, Liverpool.

INDIAN MEDICAL SERVICE.

Col. W. C. H. Forster to be Maj.-Gen.

Capt. A. V. Lopes to be Maj.

Lt. P. J. Kelly to be Capt.

Special Articles.

GAUGING THE HOOKWORM LOAD OF A COMMUNITY.

By CLAYTON LANE, M.D.,

LIEUT.-COLONEL, INDIAN MEDICAL SERVICE (RETD.).

It is customary, before beginning anti-hookworm work in any community, to gauge its hookworm load by egg counts. The underlying assumption is that egg counts form a dependable index of the number of worms present.

A series of observations made by different persons during the last few years, but not necessarily made with that object in view, have thrown considerable light on several factors which influence the worm-egg ratio and are worth considering in some detail. But the ground must be cleared by certain preliminary comments.

First, nearly all egg counts have been made by methods whose individual accuracy is not admitted except by their sponsors or their sponsors' associates. That does not imply that when carried out on a large scale they do not allow of conclusions correct enough for the purpose considered in this paper. Secondly, no anthelmintic can be depended on to expel all worms, so that when using this means of obtaining and counting worms it is necessary to know and to state whether all worms can reasonably be assumed to have been expelled, and if not, what proportion remains. To attribute to a given number of worms an egg output really produced by quite a different number does not further knowledge.

Illness of the Host: Anthelmintics.

Both these extraneous influences on female hookworms may stop or lessen oviposition. An egg count on an obviously sick man, especially one with an intestinal complaint, is not reliable. Oil of chenopodium, for example, may influence oviposition for a fortnight after its administration. Accordingly, no egg counts must be made within that period of treatment if their object is to determine how effectively an anthelmintic has reduced the worm load of a community, nor should they be made during any epidemic.

Size of the Stool.

If two men harbour the same number of hookworms which oviposit at the same rate, but if the food of one man results in 100 g. of faeces daily and of the other in 200 g., the number of ova per gramme of faeces will be twice as great in the first as in the second; the size of the stool varies with personal and racial habits of feeding. But it varies also with the age, or rather with the size, of the host, for a child's stool is smaller than that of an adult, and there is nothing to suggest that the egg output of the female hookworm is less in one than in the other. Failure, then, to allow for the size of the stool will make inexact any attempt to estimate by egg counts the worm load of a community, and, if in addition the stools counted include those of children, this error will be increased. It may be noted, in passing, that this egg concentration in small stools will make less inaccurate the less accurate diagnostic techniques, so that when these are used merely to find out the number of persons

infected they will show a higher percentage in children than in adults when both carry the same relatively small number of worms. There are, of course, some infections so heavy that no technique can miss them.

Age of the Infecting Worms.

C. A. Herrick,¹ for *Ancylostoma caninum* in dogs and M. P. Saries² for *A. braziliense* in dogs and cats, have shown that the daily output of eggs increases from the date when they first appear until a maximum is reached. That this occurs in man was shown by A. Looss in 1902 and 1903.³ He examined at intervals about 0.01 c.cm. of faeces in suspension obtained from a man whom he had deliberately infected. Eggs were first found in this quantity of faeces about ten weeks after infection; they then numbered two, and eight weeks later had steadily increased to 31, remaining at about this level for months.

It follows that in those areas in which acquisition of infection is seasonal, the same egg count at different seasons, will be brought about by a different hookworm load; the one will form no constant measure of the other. In some parts of the world subject to hookworm infection, variations in climate make it likely that hookworm infection is acquired at certain seasons only, in other parts that acquisition is seasonally intensified.

Consistency of the Stool.

By his caustic soda method N. F. Stoll⁴ counted the eggs in stools of seven persons, four passing formed, two passing mushy, and one passing liquid stools. Each received two treatments with 1.5 c.cm. of oil of chenopodium and the worms were collected by sieving through a wire mesh of 40 to the linear inch. Of only three cases is it reported that there was subsequent examination to determine the fact or extent of residual infection, and even in them the interval between treatment and re-examination is not stated. In the paper in which he reported these cases Stoll writes: "This dilution technique, subjected to continual scrutiny, only fosters the conviction that when properly used it constantly delivers counts even in light infestations correctly." The inference drawn by readers has probably been that this statement includes these post-treatment examinations. It is clear, of course, that, accepting Stoll's own conclusion noted below—namely, that a mushy stool contains 22 eggs for each gramme when a single female is normally ovipositing—there will still be inaccuracy even after examining from the same stool as many as seven specimens of 0.005 g. each, a number of specimens which few, if any, do examine, and a quantity of stool for each specimen which Stoll and Hausheer now advise.

Examinations in light infections have been reported by W. C. Sweet⁵ and by P. A. Mapleton and A. K. Mukerji.⁶ Sweet used the modification of Stoll's technique advised by Stoll and W. C. Hausheer,⁷ and wrote: "In obtaining the average egg count all persons who gave no egg by the Stoll method were included in a zero count although a considerable portion of them showed eggs by the Willis method." Mapleton and Mukerji carried through several series of post-anthelmintic counts; only one need be quoted: "Eight of the 12 cases were negative to Stoll's count, whereas only one did not contain eggs as demonstrated by Lane's method"—that is, by direct centrifugal flotation (D.C.F.). Stoll's post-anthelmintic counts did not, then, really measure the residual infection, which he claimed to be 0, 2, and 6 per cent., even in the three cases in which he reports having attempted it.

R. B. Hill's⁸ similar but more exact work may well give a better idea of the real state of affairs. After egg counts Hill gave to 402 persons one treatment by 2 c.cm. (M 30) of oil of chenopodium and two others each by 4 g. (grs. 60) of thymol (a far more stringent regime than that used by Stoll), demon-

strated the presence of persistent infection by Willis's gravity flotation method, and estimated its extent by Stoll's. Among those who refused to take more than these three treatments the egg counts after them were 33 per cent. of the originals. This matter has unfortunately to be stressed because, non-evidential as they are, it was on these four formed stools (confirmed by two others giving a somewhat higher rate) that Stoll concluded that each female necator produces eggs at the rate of 44 to each gramme of formed faeces, on these two mushy stools that the figure for that consistency was put at 25, and on this single diarrhoeic stool that it was taken as 12 for watery motions, a proportion of 4, 2, and 1. The matter did not end there, for it has become almost obligatory for any one the world over, who wishes his investigation to appear serious, to adopt this ratio, and to express the worm load of a community as if all were passing faeces of one consistency, multiplying his individual counts by the appropriate figure. The need to do so does not, of course, emerge from these meagre data.

The conclusions of other persons are interesting. Docherty,⁹ using Stoll's egg-counting method in Ceylon, found that the egg-worm ratios he obtained for formed, "soft-formed," and mushy stools were as 52, 48, and 40; if 52 is correct for the first, the last should, of course, have been 20 if Stoll's formula held. Herrick¹ found that in dog's faeces there was no relationship between stool consistency and the egg-worm ratio. The work of Augustine and his colleagues¹⁰ is particularly interesting. Using the Stoll-Hausheer counting method, they agreed that Stoll's relationship of 1 to 2 between the ovum content of mushy and formed stools held for *A. duodenale* in Egypt, but stated that for *Ascaris lumbricoides* in that country it was 1 to 3. That is to say, the same faecal material of the same consistency habitually diluted one faecal constituent twice and another three times. This is impossible. Here, too, the suggested ratio cannot be accepted.

Insofar as it is water which, by dilution of solid matter, causes alteration in consistency, I have made the following investigations.*

The stool examined was spread thinly out within a small evaporating dish so that exactly 1 g. (measured to within 0.01 g.) was added to the dish. This was then placed on a boiling water-bath until the faecal smear was quite hard. The percentage of solid matter remaining after the water was driven off was as follows: liquid stools, 3, 6, 6, 8, 8, 8, 9, 10, 12, 15, average 8.5; mushy stools, 10, 13, 15, 17, 18, 20, 20, 22, 23, average 17.8; formed stools, 18, 20, 22, 23, 26, 32, 33, average 24.7.

One liquid stool may then have five times as much solid matter as another and more than has a mushy stool; one mushy stool may have more than twice as much solid matter as another and more than has a solid one; and one solid stool may have nearly twice as much solid matter as another. The average solid matter of liquid and mushy stools was in this series as 1 to 2, but it seems optimistic to regard this as more than fortuitous; while the average ratio of solid matter in mushy and formed stools was far from being as 2 to 4. Clearly in these cases it is not through any dilution of solid matter by water that the Stoll formula of multiplication can be justified in stools of different consistency. There is, then, strong evidence that stool consistency does not produce variations in the worm-egg ratio sufficiently exact or constant to demand allowance in estimating the worm load of a community. Indeed Herrick found that when he made such allowance in dogs his results became erratic. In our present state of knowledge no such general formula is admissible; if in any locality an observer elects to use one, the responsibility rests with him to show first that it is locally applicable. The wide acceptance on this exiguous foundation of the need to allow for stool

* Part of work, under a grant from the Royal Society, carried out at the Seamen's Hospital Society's Hospital, Royal Albert Dock.

consistence by a definite formula is an illuminating illustration of the weight carried by authority in certain specialties, at least within tropical medicine, and shows how grave is the responsibility of anyone who may wield that authority lightly.

Intensity of Infection.

For *Ancylostoma caninum* in the dog, Sarles¹¹ found that as infections increased in weight each female worm laid fewer eggs. In one series each female produced 26,800 eggs daily when infection was by 16 of them; when it was by 187 females each laid 4500 eggs daily. With the number of worms increased twelvefold the fertility of each was reduced to a sixth, so that the total egg output was only doubled. It was clear to me that if anything of the kind held for man, no present or past attempt to measure the worm load by egg counts approached accuracy, and with this in mind it occurred to me to analyse the figures in R. B. Hill's tables,¹² the only material, so far as I knew, by which the matter could be tested. This work was executed in Florida in Porto Rico with great care and under close supervision, and was published with a well-based belief that all stools concerned had been obtained.

In a number of adults the total faecal deposit was collected for either two or three days; by Stoll's egg-counting method the total number of hookworm eggs passed during each day by each person was estimated; each person was treated with 3 c.cm. of carbon tetrachloride and worm counts were made from the faeces passed for the next 48 hours; two gravity floatation (Willis's) examinations were made and the positive cases egg counted as before; whether found infected or not all cases received a second treatment, this time by 3 c.cm. of oil of chenopodium, and worms were again collected. Incidentally, it may be noted that only in 40 per cent. of cases were no worms recovered by the second treatment, so that the full dose of carbon tetrachloride (which dose has killed) left 60 per cent. of persons still infected. Two further examinations by Willis's technique passed 93 persons as disinfested.

From the very full details published regarding these 93 adults it is possible to discover the average egg output of each female necator in different grades of infection. When there were fewer than 300 female worms (average 111) the average daily egg output of each was about 4000, when it was between 300 and 600 (average 444) the egg output was about 2500, while when there were over 600 (average 897) the figure was about 1500. In other words, with the degree of infection increased fourfold the total number of eggs increased two and a half fold, with infection increased eightfold eggs increased only threefold. In the heaviest grade of infection it took eight worms to produce as many eggs as did three in the lightest, while as between medium and heavy grades, doubling the number of worms increased the egg output by 20 per cent. only. Two points are noteworthy: had Hill not published his protocols, his careful valuable work could not have been used to check for man Sarles's investigations on dogs; and, second, his work confirms Sarles's findings that with an increased load of infection each female hookworm lays fewer eggs. The conclusion is that the egg output cannot safely be used as an accurate measure of weight of infection of a community, nor, of course, of the extent to which mass treatment has been effective.

Species of Hookworm.

The work of Stoll and of Hill quoted above was on necator infections. From the inmates of a lunatic asylum in Queensland hookworms were recovered to the extent of 20 per head, 91.1 per cent. being ancylostomes. Sweet¹³ re-examined the inmates 18 months later and, using Stoll's counting method and consistency formula, judged that they had become reinfected to the extent of 75 female worms apiece. This he held to be unreasonable. He did not, however, question either the technique or the formula, but concluded that ancylostomes laid five times as many eggs as necators.

W. W. Cort et al.¹⁴ used Stoll's counting method for determining the egg-worm ratio of about 50 cases in a district of China. Stools were computed to average 100 g. This must be compared with 222 g. in the four cases on which Stoll announced that the female necator laid 44 eggs for each gramme of a formed stool, and which gave a daily output by each female of 9008 ova. The average daily total egg output by each female worm in China was 20,000, the ratio of necator to ancylostoma was as 2 to 3, the egg output of each female necator had been put as about 10,000, so that each female ancylostoma was producing 27,000 eggs daily. The paper does not, however, note the anthelmintic used, nor whether there was any attempt to determine that it produced disinfestation, so that the egg-worm ratio rests here too on an unscientific and precarious basis.

In one case of pure infection by each species of parasite Soper¹⁵ found the daily egg output by each female ancylostoma to be about 20,000, and of each female necator to be about 10,000. Treatment was carried to microscopic cure as tested by D.C.F., used, however, without its efficient comminutor and probably not fully reliable; at the same time, for 25 female ancylostomes there were recovered only seven males, a rather unusual ratio. Soper sought confirmation of this 2 to 1 ratio by mincing up the bodies of 50 females of each species and counting their unladen eggs. They also were present in about that ratio after the worms had been recovered by oil of chenopodium, alone or combined with carbon tetrachloride.

Augustine et al.¹⁶ investigated the egg-worm ratio in Egypt where *A. duodenale* alone is present. Cases were treated with 3 c.cm. of carbon tetrachloride and 1.5 c.cm. of oil of chenopodium. The Stoll-Hausheer technique was used to make counts before and after treatment. More than one count was usually made on each occasion, or, in other words, the amount of stool examined was not invariably more than 0.005 g. The table given in the paper is not easy to understand (the number of cases is cited equally as 74 and 311 and the symbols are not all explained), but it seems that when two faecal preparations were examined an egg was found in only one of them in 38 per cent. of all cases—that is, one egg in 0.005 g. of faeces. The findings were brought to the basis of formed faeces, the formula for which, as noted above, was held to be different for hookworms and ascaris and so is quite unacceptable. It was concluded that the female ancylostoma lays eggs at the rate of 238 for each gramme of faeces. The size of the faecal output is unstated, and the paper does not contain the protocols which would enable others to form their own conclusions as to the value of the observations. At least the conclusion is precarious.

Evidence as to the relative ovipositing power of ancylostomes and necators is, then, meagre, but such as there is, together with the relative bulk of the two worms, suggests that it will prove to be about as 2 to 1.

Conclusion.

It has been seen that general health, size of stools, seasonal or continuous acquisition of infection, intensity of individual infection, and the species of worm concerned may all greatly influence the hookworms' egg output and ought all to be taken into account in attempting a true estimate of the worm load of a community; and that the question of consistency of stool on which so much stress is being laid is an uncertain and inadequately measured factor which has been quite unduly emphasised. It follows that egg counts have not hitherto measured dependably the worm load of a community and can only be made to do so with great difficulty. For certain investigations accurate egg counts are essential; they have indeed been in the past, and will be in the future, of the greatest value. But, as usually undertaken with the idea of obtaining the real measure of the worm load of a community, particularly the load before and after mass treatment, it

must be concluded in our present state of knowledge that they are, in spite of their reassuring appearance, of accuracy, a waste of time and money.

THE RISE IN SICKNESS CLAIMS IN THE INSURED POPULATION.

INVESTIGATION BY THE GOVERNMENT ACTUARY.

Sir Alfred Watson, the Government Actuary, has made an examination of the sickness and disablement experience of a group of approved societies in the period 1921–27, and has reported¹ the result to the Minister of Health as chairman of the Joint Committee of National Health Insurance. A previous analysis of the sickness and disablement experience in the years 1921–23 of a representative sample of the whole body of insured persons was made for the Departmental Actuarial Committee set up to advise the Royal Commission, and was published as an appendix to the report of the Commission. The original sample included some 500,000 men and 400,000 women whose experience was followed through three years 1921, 1922, and 1923. On the present occasion it was regarded as adequate to work upon the experience of societies including about 50 per cent. of the membership in the original sample with the added precaution of taking out the experience of the new sample for each of the years 1921, 1922, and 1923 as well as for the subsequent years, so as to show the experience of a particular and representative group of societies for each year from 1921 to 1927. The membership at the last valuation date of the societies in the new sample comprised 219,000 men, 172,000 unmarried women and 61,000 married women. The latter were thus 27 per cent. of the total number of women, a somewhat higher proportion than that found in the insured female population generally, but from the present point of view the difference is immaterial, separate analyses having been made throughout of the respective experiences of the married and the unmarried. Widows are grouped with spinners under unmarried women.

Upward Movement of the Claims.

The percentage of the actual weeks of sickness and disablement benefits respectively, in each year, to the corresponding provision made for these benefits by the present valuation basis is shown in Table I.

It is explained that this provision is such as to reproduce, in the case of men, the expenditure which would be incurred if the claims were in agreement with the Manchester Unity experience, 1922–27, due allowance being made for the exclusion of the first three days. A small adjustment is made, in accordance with the present basis of valuation, to assign rather less of the claims to sickness benefit and rather more to disablement benefit than the actual Manchester Unity rates would indicate. As the total cost provided for on the new basis is the same as would be incurred on the Manchester

Unity standard without any adjustment, while an increased proportion of the claims is assigned to disablement benefit, it follows that the total quantity of incapacity provided for is slightly more than that shown in the Manchester Unity Tables.

In the case of women the basis is the actual experience of the "Selected Societies" in the year 1923 (as obtained in connexion with the work of the Royal Commission) with an addition of 10 per cent.

TABLE I.—Percentage of Weeks of Sickness to "Expectation."

Year.	Men.		Women.			
	S.B.	D.B.	Unmarried.		Married.	
			S.B.	D.B.	S.B.	D.B.
1921	76	54	73	60	63	66
1922	89	65	88	67	83	73
1923	86	72	91	77	92	78
1924	97	81	105	86	110	104
1925	98	83	112	99	121	125
1926	108	93	112	111	124	146
1927	107	100	117	119	130	171

S.B. and D.B. = sickness and disablement benefit respectively.

From Table I. it will be seen that in respect of each of the three classes of insured persons the claims for both sickness benefit and disablement benefit have been rising continuously during the seven years. Comparing 1927 with 1921 the claims for sickness benefit have risen in the case of men by 41, of unmarried women by 60, and of married women by 108 per cent. For disablement benefit the corresponding increments are 85, 100, and 159 per cent. In the early years of the period the moderation of the claims was, says the Actuary, a factor of substantial importance in the production of valuation surpluses. Since 1926 in the case of men, and 1924 in the case of women, the position in this respect has undergone a serious change.

Their Number and Duration.

Two factors enter into the average rate of sickness or disablement: (1) the proportion of members who make a claim, and (2) the average length of the period over which the claim lasts. If the claims are rising and it is desired to analyse the cause it is obviously necessary to examine each of these factors, as is done in Table II., the figures in which relate to all ages from

TABLE II.—Analysis of Claims with Reference to Number and Duration.

A. = Weeks of claim to each 100 members.
B. = Number of members claiming in each 100.

16 to 65 combined. It will be seen that the average duration of claims (per claimant) for sickness benefit within the year has not altered greatly in the seven years as respects either men, unmarried women, or

¹ National Health Insurance. Cmd. 3518. H.M. Stationery Office, 1930. 4d.

married women. The average for men may be put at four and a half weeks, for unmarried women at something under six weeks, and for married women at something more than seven weeks. On the whole the tendency is downwards in the case of men and unmarried women. Among married women it is rather the other way. The significant fact is the growth in the number of claimants. In this respect the years 1921 and 1927 show the two extremes. Taking men, it is seen that, while 14 out of every 100 claimed sickness benefit in 1921, the proportion had grown to 23 in 1927. Among unmarried women the respective proportions were 12 and 21, and among married women 19 and 38. The growth in the intervening years, though not regular, was practically continuous. The position as to disablement benefit is similar, save that the growth is more regular. The average duration of disablement benefit tends to increase among men but not among women. Indeed, the average duration of disablement benefit among married women shows a tendency to diminish, though it may be surmised that this is due rather to the increasing proportion of cases of recurrent claims by women who had previously exhausted their right to sickness benefit, and who were accordingly paid at the disablement rate, than to any shortening of the duration of the really protracted claims. The average duration of disablement benefit within the year in 1927 was between six and seven months per claimant in the case of men and unmarried women, and about five months in the case of married women. The significant feature again is the growth in the number of claimants. Among men the claimants for disablement benefit increased from 15 per 1000 members in 1921 to 26 per 1000 in 1927. Among unmarried women the respective figures are 19 and 39, and among married women 33 and 92. The general position as to married women is very striking; in 1927, of every thousand such women 380 drew sickness benefit and 92 disablement benefit. Of the 92, some 42 drew both sickness and disablement benefit. Of every thousand married women therefore, 430 drew either sickness benefit or disablement benefit or both in 1927.

The Effect of Age.

The question arises as to whether the continuous increase in the number of claims, while their average duration remains the same, is general, or whether the element of age is significant in regard to them. Two tables in the report show the number of claimants for sickness and disablement benefit respectively per hundred members in each age-group in the years 1921, 1924, and 1927 (figures being given separately for men, unmarried women, and married women) and the average duration of claim (per claimant) within the year. The growth in the number of claimants for sickness benefit is, then, seen to have prevailed in all age-groups; this applies equally to men, to unmarried women, and to married women. Between 1921 and 1927 the increase is roughly 60 per cent. throughout among men, 75 per cent. among unmarried women, and 100 per cent. among married women. While the experience of the year 1924 occupied an intermediate position it was distinctly closer to that of 1927 than to that of 1921. The position as to claims for disablement benefit is indistinguishable from that of the sickness claims. In both cases there is a universal increase in the numbers claiming.

So far as disablement benefit is concerned it is explained that in the early years of the system a regular increase in the number of the permanently sick was expected and was provided for in the finance of the scheme. Since National Health Insurance was applied compulsorily to those who were in employment on July 15th, 1912, or who entered employment later, the insured population at the outset included no persons who were already disabled; cases of permanent invalidity among the insured would therefore begin at a very small number and would continuously increase until a stable condition was reached, and the insured population had accordingly become normally constituted from this point of view. The period during which the number of permanent invalids would accumulate was actuarially estimated at about ten years, and while the disturbance of

industrial conditions set up by the war may perhaps have resulted in its extension, it is improbable that it went on till 1927. In any case this factor, even if it were still operating in that year, would only serve to explain a moderate increase at the higher ages in the number of recipients of disablement benefit; it could not account fully for the increases shown from, say, age 40 onwards. At the younger ages, where the feature is equally marked, this theory of "natural causes" is still less available as an explanation of the increase in the claims for disablement benefit. Among unmarried women aged 25 to 29, 1.7 per cent. drew disablement benefit in 1921 and 3.0 per cent. in 1927. A preponderating number of the group who were of these ages in 1921 had been insured for nine years (having all been aged 10 and upwards in July, 1912), while those who were of the same ages in 1927 had probably been insured on the average for about ten years. It is obviously quite impossible that the addition, on average, of something between one and two years to the period of insurance in which permanent incapacity could have developed would explain an increase which almost doubles the relative number of the recipients of disablement benefit in 1927 as compared with 1921.

The tables show further that while, in regard to men and unmarried women, the average duration of a claim had fallen perceptibly at ages under 45 between 1921 and 1927 the difference at the higher ages was very small, and on the whole represented an increase rather than a decrease. In these circumstances some further analysis seemed desirable. A distribution of the claims to sickness benefit of men in the years 1921 and 1927 was accordingly obtained.

This analysis was limited, by practical considerations, to cases in which sickness benefit arose in the year of record and was subject to the three days' waiting period. It accordingly excluded cases in which sickness was current at the beginning of the year and cases in which a claim arising in the year was linked up with one that ended in the previous year. There was also excluded a very small class in which the claims, while beginning in the year and being subject to the waiting period, ran on beyond 26 weeks. These limitations on the data were not considered likely to diminish such value as the results might have. The analysis was adjusted to eliminate the disturbance due to the fact that the membership of the sample increased fairly substantially in the seven years.

Analysis showed that at the ages under 45 the number of claims of very short duration increased very greatly, the maximum being an increase of 88 per cent. in respect of claims of over two and under three weeks. For claims of longer duration the increase was smaller. After the first four weeks' sickness there is a quite definite drop in the excess of 1927 over 1921, the decrease continuing as the duration advances. At the ages 45 to 54 the greatest amount of excess is still at duration two and under three weeks. A decrease in the excess as duration advances is not pronounced in this section except in claims of a duration of thirteen weeks and upwards. At the highest age-group (55-64) the percentage increase in 1927 over 1921 is irregular and there is no significant trend among durations up to thirteen weeks. After the duration of thirteen weeks there is a definite drop.

General Conclusions.

The chief conclusion drawn by Sir Alfred Watson is that a continuous growth in the number of persons claiming benefit has been experienced, and that the increase is most pronounced, on the whole, in the claims of short duration. With reference to the question whether these features are persisting, he finds that the claims for sickness benefit in 1928, taken over the whole insured population of Great Britain, were about 91 per cent. of the claims of 1927 in the case of men and 94 per cent. in the case of women. On the other hand, the experience of 1929, as indicated by the first 39 weeks, payments of a number of societies covering nearly 50 per cent. of the insured population, shows a serious rise, in the case of both men and women, over the corresponding period of 1928. Disablement benefit shows a further rise of a few points in the case of both sexes in 1928, and a slight increase in 1929 over the level reached in 1928. Taking both benefits together, it must be concluded that the conditions of 1927 have not subsequently been alleviated.

Sir Alfred Watson has confined his report, as far as possible, to a statement of the statistical results of the analysis which he has conducted. The various questions to which the results may give rise are, he adds, matters for administrative deliberation and, doubtless, for consultation with the medical profession and the governing bodies of the approved societies.

Disablement Benefit: Two Special Inquiries.

Certain statistics obtained in the course of the work of the Actuarial Committee which advised the Royal Commission, suggested that inquiry might profitably be made in regard to two points: (a) the extent to which insured persons "declared-off" the funds of approved societies soon after benefit was reduced from the sickness rate to the disablement rate; and (b) the extent to which such persons subsequently became claimants for either sickness or disablement benefit. Sufficient data to enable these questions to be examined were accordingly obtained and analysed, and the results are given in the following paragraphs.

Question (a).

An examination was made of the cases, numbering 7155, in which recipients of sickness benefit in the year 1927 had passed on to disablement benefit. The cases were almost equally divided between men, unmarried women, and married women, the respective figures being: men 2320, unmarried women 2250, and married women 2585. These figures are in themselves somewhat arresting, considering that the relative proportions in which the three classes enter into the sample experience are: men 49 per cent., unmarried women 37 per cent., and married women 14 per cent. They may be regarded as a corollary to the facts that in 1927 the average duration of sickness claims over a large part of the table was about 50 per cent. higher among unmarried women, and from 50 to upwards of 100 per cent. higher among married women, than it was among men. Of the 7155 persons who entered on disablement benefit during 1927, 3997 "declared-off" within the year; of the remaining 3158 cases 220 died during the year, and 2938 were still drawing benefit on Dec. 31st.

The results show that (1) a high proportion of "recoveries" after entry on disablement benefit is common to both sexes and to all ages, but (2) the proportion is much heavier at the younger ages than at the older, and (3) is specially heavy, at any rate up to the age of 50, among married women. The fact that the "recoveries" do not include the cases in which the recipient came down to the disablement rate late in 1927, and "declared-off" early in 1928 emphasises the conclusion to be drawn from this table.

It remains to be considered for what periods the insured persons who "declared-off" continued to draw benefit after being reduced to the disablement rate. Of all claimants who passed from sickness benefit to disablement benefit in 1927, and ceased to draw benefit before the end of the year, more than one in six went off the funds almost immediately the benefit was reduced to the disablement rate. Within a month of the reduction 50 per cent. had been certified as capable of work, and within eight weeks 70 per cent. had found their working capacity restored.

Question (b).

The Government Actuary states the results of a statistical examination of the "after-history," in regard to claims, of those persons who "declared-off" disablement benefit in the course of the year 1924. The period of examination is limited to the years 1925 and 1926. There were 5063 such cases, of which 630 had again returned to benefit before the end of 1924 and were still on the funds at the end of the year. These 630 cases have not been further investigated: they are part of a group of intermittent claimants, of the existence of which the facts relating to the 4433 cases in which the "declaration-off" was followed by no further claim during the year will afford sufficient evidence. Of the 4433 cases it should be explained that in 3597 cases the insured person had "declared-

off" disablement benefit only once in the year. In 830 cases, on the other hand, there had been at least one previous "declaration-off" disablement benefit within the year, followed by a renewed claim to this benefit; it was the termination of this subsequent claim within the year that brought the case within the scope of the present section of the inquiry. There is no great difference between the sexes or between the two classes of women in regard to the point now under investigation. Of 4433 persons who ceased to draw disablement benefit in 1924, 1851, or no more than 42 per cent., did not claim benefit in the next two calendar years. Analysis of the 2579 persons who returned to benefit in 1925 and 1926 after ceasing to draw disablement in 1924, showed that 1218, or approaching 50 per cent. of them, came back on the funds in 1925 and, having been capable of work for less than a year, were again placed on disablement benefit. So far as questions of supervision are concerned cases of this type are, says Sir Alfred Watson, probably not specially significant, but it is doubtful whether the same view should, in general, be taken of cases in which, after drawing disablement benefit, the insured person "declared-off" and subsequently claimed again after an interval not much exceeding the minimum necessary to enable him (or her) to qualify for the full sickness benefit. It would seem probable that such cases represented fully 15 per cent. of all who relinquished disablement benefit in 1924.

THE BELLE VUE SPA, TREFRIW.

OPENING OF THE PUMP ROOMS.

THE therapeutic properties of the water of Trefriw have been known for more than half a century, but like other natural waters it tends to lose these properties on exposure to air, and for that reason its value has probably been under-estimated in the past. At the Belle Vue Spa, which was opened on April 26th by Sir Arbutnot Lane, the water is collected in an old Roman pyrites mine, where it drips from the rock into funnels which lead into large containers. To prevent contact with the air there is a layer of liquid paraffin on the surface of the collected water; bottles are filled from the containers by means of pipes, care being taken to exclude air bubbles, and a large tank is fed from the containers, in which it is intended to store water for baths. Mr. Carel Hoeftke, who has played an important part in establishing the new centre, is considering a method for bottling under water, suggested by Dr. Judd Lewis, who has been asked to advise on the best means of preserving the physical properties of the water during transport. It is believed that with suitable precautions the water can be bottled so that it will preserve its therapeutic value for a long period.

Qualities of the Water.

The water of Trefriw differs from most natural waters in containing iron in the form of ferrous sulphate and not as the carbonate. It also contains silica, which is unusual, and free sulphuric acid, but does not contain ferric salts, copper, nickel, or zinc, and no high proportion of aperient salts or sulphuretted hydrogen. The strength of the Trefriw water varies in different streams, but is such that it is only surpassed by the Matchless well in Alabama; similar springs in Germany, Sweden, Scotland, and the Italian Tirol have a lower concentration of ferrous sulphate in their waters. The Trefriw water is to be standardised at gr. 1 of ferrous sulphate per 3i, and the dose will be 3i; taken in larger quantities the water acts as an irritant and may produce symptoms resembling dysentery. The origin of the water is thought to be a lake some three miles away, whence it percolates through the iron-impregnated rock to the old pyrites mine.

The pump room of the new spa stands on the banks of the river looking towards the famous Trefriw

valley. Like the house in "Peter Ibbetson," it might be called "Parva sed Apta"; at either side of the central pump room are baths and dressing-rooms, and parts of the main room can be curtained off for special treatment. Massage, manipulative and light treatment will be carried on under the supervision of Dr. Williams, who has been in practice near Trefriw for many years. The free sulphuric acid of the water gives it some of the same properties as the acid waters of New Zealand, when used for baths; it has a local irritant action which causes reddening of the skin and increased circulation in the peripheral capillaries.

The Opening Ceremony.

Sir ARBUTHNOT LANE, in his opening address, spoke of his personal debt to the managing director, Mr. Hoefftke, whose view that inflamed joints should be treated by traction and movement he had on many occasions adopted, with beneficial results to his patients. Trefriw, he said, had once been a famous beauty spot to which visitors came yearly, but for some unaccountable reason its popularity had declined, and with it the prosperity of the inhabitants. It was to be hoped that among its other advantages the new spa would restore the old prosperity to Trefriw. The climate of the valley was particularly suitable for the treatment of rheumatoid arthritis and other joint affections, and this, combined with spa treatment, should help to make Trefriw one of the most important health resorts in Great Britain.

Dr. FORTESCUE FOX said that the interest of scientists was becoming awakened to the value of physical treatment. The water of Trefriw stood at the head of all waters containing ferrous sulphate in Europe, and was only exceeded by the well in Alabama. The value of these waters lay in the highly assimilable form of the iron, a quality which was lost on exposure to air. As usually happened with natural waters, the properties had been discovered by the inhabitants.

auspices. As early as 1757 Dr. John Rutty, of Dublin, had published a book ("A Methodical Synopsis of Mineral Waters") deploring the spread of German spa waters with consequent decrease in the use of English and Irish waters. In describing the properties of natural waters he had observed that the native qualities of some were only obtained at the

Terrace of Belle Vue Spa with the village of Trefriw.

fountain, that those who took the waters should not also take tea, that a milk diet appeared to be helpful during a course of treatment, and that persons who felt the cold could take the waters warm in bed in the mornings with advantage. He had gone on to say that these natural waters, though they seemed to be but weak tinctures of iron, had subtle qualities which gave them more power than artificially prepared waters. These observations of Dr. Rutty were as sound to-day as they had been in the eighteenth century. The therapeutic value of natural waters rested on a valid basis, not on account of their chemical composition, but on account of the energy they introduced, and their power of assisting the elimination of waste products. When the waters

The view from the terrace overlooking the Conway.

(Photos by L.N.A.)

so that a local tradition became attached to the place. In France the discovery of a natural spring of this type would lead to investigation by the Commission des Eaux Minérales, and the official establishment of a health resort. No such advantages were to be had in England; he would like to see all British natural waters developed under official

left the fountain they underwent changes not in chemical but in physical composition. To have their full value they should be under chemical study and supervision, such as Dr. Judd Lewis was undertaking for the waters of Trefriw. A continental authority on natural waters had described them as being of value to the lymphatic, the neuropathic, the dyspeptic,

the convalescent, the tropical invalid, the tired brain worker, and the arthritic. Bath treatment would have its place at the new spa, and certain cases would benefit both by the waters and by manipulative treatment. Dr. Fox concluded with a quotation from Dr. Rutty: "How much could be done if our own people could be persuaded to lay aside their unrighteous prejudices against the productions of their own country."

Major GORONWY OWEN, Member of Parliament for Carnarvon, who took the chair, said that the decline in prosperity of Trefriw of late years, in spite of attempts to improve conditions, had been progressive. The new spa should give an opportunity for the town to reinstate itself.

Sir ARBUTHNOT LANE illustrated the difference between natural and artificial waters by a reference to sea water. Salt water, chemically indistinguishable from brine but artificially prepared, was fatal to fish. But if 2 per cent. of true sea water were introduced into the solution, fish could live in it without difficulty.

At the conclusion of his speech Sir Arbuthnot declared the spa open.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

The Aberdeen Chair of Medicine.

ON the recommendation of the Secretary of State for Scotland the King has appointed Dr. Leybourne Stanley Patrick Davidson to be Regius professor of medicine, in the University of Aberdeen in the place of Prof. Ashley Watson Mackintosh, who has resigned.

Dr. Davidson, who was educated at Cheltenham and Trinity College, Cambridge, is 36 years of age and served with the Gordon Highlanders for three years during the late war, reaching the rank of captain. He was severely wounded and returned to his medical studies at Edinburgh in 1917, graduating with first-class honours two years later. He gained the gold medal for his M.D. thesis in 1925 and was elected a Fellow of the Royal College of Physicians of Edinburgh. Since 1927 he has been assistant physician to the Royal Infirmary, and for the past two years he has also been lecturer in systematic and clinical medicine in the university. After holding resident appointments he worked for three years in the department of bacteriology, and his earlier publications were largely bacteriological. His recent papers include several on pernicious anaemia published in *THE LANCET*, and a book on the same subject written in collaboration with Prof. Loyell Gulland.

Medical Service in the Highlands and Islands.

Your correspondent, "Viator" (April 26th, p. 939), calls attention to the absence of any superannuation assistance under the Highlands and Islands Medical Service. The Dewar Committee contemplated that, under a special scheme, it might be possible to enable certain parochial medical officers to retire. But it certainly made no recommendation about a contributory scheme of any kind. It is to be remembered that, under the Statute, each of the medical practitioners in agreement with the Highland and Islands Board (afterwards with the Board of Health, now the Department) was and is dealt with as an individual. No special schemes were ever approved for superannuation, or an allowance on retirement. In one or two extreme cases, I am informed, it was arranged to provide a parish with a second medical officer to overtake the more distant work, so relieving the older principal, whose obligations now covered a much smaller area. But no general arrangement of any kind was ever in force. If a contributory system were contemplated, the methods of subsidy would have to be materially altered.

"Viator" hopes "now the financial conditions are adequate, that a satisfactory scheme for superannuation of the medical officers will be granted by the Department in the interest of the efficiency of this essential medical service." It is proper to state that the Highlands and Islands Medical Service is not a whole-time State medical service. Under the various schemes subsidies are given to individual doctors in private practice and in no case does a man's whole salary come from the Fund. The practices are classified roughly into two types: First, where it is not possible for the doctor to earn a reasonable living for work done, the Fund supplements the salary to an accepted minimum net income. The number of these practices in 1923 was 35. Secondly, in other cases, the practitioner is compensated for such loss of income as he would incur if he attended distant patients at the same fee as near patients, these fees being specified by the Department. There are many large practices with poor areas. These practices would not normally require a subsidy; but the attendance on the more necessitous districts can be carefully estimated and compensation made on this estimate. The doctors must furnish details of their income confidentially and, where necessary, the amount of the subsidy is discussed confidentially with an officer of the Department. In this way arrangements have been made satisfactorily to the practitioners, and the Department are enabled to maintain an efficient practice.

On the terms of this system of subsidised individual practices a superannuation scheme would be somewhat difficult to frame. But, under the new Local Government Act, another factor will enter into the case—namely, the consolidation of all the medical services under a large county authority. These official services will include the ordinary public health services, public assistance (medical), school health, maternity and child welfare, and the nursing services attached to all these. It will include also specialist services—surgical, medical, and dental. Schemes are already in existence under the H. and I. Fund to cover such specialist services and in each of three centres a consulting and operating surgeon has been established, chiefly at the expense of the Department. No doubt other such arrangements will ultimately follow. The re-grouping of hospital services will help this process. When the transitions to the new system are complete, it may become possible to establish at least a pro tanto superannuation scheme to cover certain officers. I believe that, although no such scheme has as yet been elaborated or even fully considered, the new conditions will compel attention to the matter, just as in the case of the medical officers of health and allied officers. Meanwhile, as indicated in the evidence laid before the late Royal Commission on insurance, arrangements are in force whereby practitioners in some single doctor areas are assisted to provide for the work of their practices during holidays. With the earmarked part of the Fund, the Department of Health are able to give assistance about once in every three years to each of the practitioners eligible for the benefit. The Department's assistance normally relieves the doctor going on holiday of his deputy's fee and travelling expenses to and from the practices. The Department have power also to assist practitioners to attend post-graduate courses of study, but, according to the latest information available, there have been no applicants for such courses. The intention of the Department was and is to make the conditions of general practice in the Highlands as nearly as possible equivalent to the conditions in the Lowlands. In the Lowlands, it is well known, there is a fund under National Health Insurance to supplement the incomes of doctors in certain necessitous areas, many of which are really as much in need of a subsidy as are many parts of the Highlands.

The new scheme of concentrated local authorities is now proceeding satisfactorily in the Highlands, and there is little doubt that the matter of superannuation and holiday relief will not be lost sight of. One broad result of the many schemes is, whereas formerly

it was difficult to get an applicant for a vacant parish medical officership, now it is no uncommon experience to have 50 or 60 applicants to choose from. It should be added that, under the Act passed last session, the supplements to the Fund must be voted from year to year by Parliament. The sum is not limited and, from the tone of the report of the Committee on the Bill and from statements subsequently made by Ministers, there seems to be a general Parliamentary understanding that the supplementary sums from year to year shall make possible a really adequate surgical, medical, and nursing service for the whole Highlands. The total population involved in the Highland area, as defined by the Statute, is only some 320,000, and the number of practitioners involved is round about 150. Many of the Highland practitioners, of course, have not agreed to come under the schemes of the Department. This was not, at least at the outset, due to any opposition by the practitioners to the schemes as such, but simply to the fact that those practitioners were fully occupied in their private practices.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Resignation of Dr. H. T. Warnock.

Dr. H. T. Warnock, who has been for 50 years medical officer of the Donegal dispensary district, has just resigned that post. His resignation was accepted with regret by the County Donegal Board of Health, the members of which gave expression to their deep appreciation of the value of his services. Dr. Warnock has, indeed, for many years held a unique position in the north-west of Ireland. He has been the leading medical man in an area of several counties, and enjoyed the full confidence of the practitioners as well as of the public over that area. Outside his own district he has been well known in professional circles. He has given long service to the Council of the Irish Medical Association, and has filled the office of president. No medical man in Ireland is held in more general respect and affection.

The late Prof. J. P. Henry.

Dr. John Patrick Henry, or Seagán P. MacEnrí, as he was known of late, who died on April 16th, at Galway, was a man of varied activities, and of success in two different careers. Born in County Sligo, and educated at Trinity College, Dublin, he practised for several years in London as an ophthalmologist. He was for a time clinical assistant to the Royal Westminster Ophthalmic Hospital, and was honorary ophthalmic surgeon to the Italian Hospital, and oculist to the London School Board and the London County Council. He was greatly interested in the language and history of Ireland, and some 25 years ago he returned to Dublin and practised as an eye surgeon, devoting all his spare time to the revival of the Gaelic tongue as a spoken language. After some years in Dublin he was appointed to the two posts of professor of ophthalmology and otology, and lecturer in modern Irish in University College, Galway, National University of Ireland. He wrote several manuals for students of modern Irish, and was for a time president of the Gaelic League. He was reputed to be a ripe scholar of Gaelic, and he was enthusiastic in the movement of the Gaelic revival. At the same time he was a man of wide culture, and did not allow his enthusiasm to swamp his common sense.

The late Dr. William Harriot Mayne.

Dr. W. H. Mayne died on April 4th at his home in Warrenpoint, Co. Down. He was born in 1872, educated at Clifton College, Bristol, and took his medical course in the Richmond Hospital and Trinity College, Dublin, where he qualified in 1896. After some time spent at sea he commenced practice in Warrenpoint. Dr. Mayne was a man of wide interests.

He was an extensive landowner, and took an active part in the political, social, and religious life of South Down. He was, moreover, a keen and prominent Freemason, and was at one time Provincial Grand Master of Down.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

The Degrees Controversy.

WHEN the scheme for an All-India Medical Council was prepared last year, the provincial Ministers were consulted. Largely, it is understood, because they were proud of their responsibilities, and feared that the scheme would interfere with provincial autonomy, they refused to accept it. The *Pioneer*, however, states that they unanimously supported the appointment of an inspecting officer, pending negotiations with the General Medical Council, and agreed to contribute funds for this purpose; but the Standing Finance Committee of the Assembly, in September, refused to assent to a token grant for the appointment, and when the question was brought forward in the Assembly itself direct opposition was at once apparent, and the proposal was dropped. Since that time, however, some progress has evidently been made. The Government of India has informed the Secretary of State that the local governments now agree that the only solution of the present difficulties is to be found in the establishment of an All-India Medical Council, and the Secretary for Education, in reply to a question in the Assembly on March 20th, undertook that every endeavour would be made to proceed with that project without any avoidable delay. But as had already been stated it would not be possible to introduce the necessary Bill during the present session. It is said that special measures are being concerted for the benefit of those students who will qualify at Indian universities during the next few months, and apart from this there is evidently no possibility of anything definite being done before the autumn. The breach is, therefore, so far as can be seen, likely to continue for some considerable time.

Feeling in the Assembly.

The fact that the critical stage of these negotiations coincided with a period of intense political unrest accounts for the failure to arrive at a provisional understanding, to tide over the period which must intervene before the projected council can become an accomplished fact. When the question was being debated in the Assembly feeling was running so high that non-medical politicians, who might under ordinary circumstances have been little interested, took it up as a useful additional plank in their platform, and it ended by being dealt with more on racial and nationalistic than on medical grounds. One regrettable feature of the controversy has been the readiness of Indian medical men of good status—some of them holding the highest British qualifications—to enter the field in an uncompromising manner against the Government, the General Medical Council, and even the Indian Medical Service, which has been several times dragged into the debate by main force, though for what reason, except the mention of the name of one officer in connexion with the proposed temporary inspectorship, it is difficult to divine. The most eminent and successful of Indian practitioners seem unable to forget or forgive the former privileged position of the Service, even when alluding to the undoubted fact that they have now succeeded in displacing these officers from many of the most coveted appointments, and in some areas have absorbed most of the remunerative practice.

Suggested Retaliation in Bengal.

The recent rupture is the culmination of a whole series of arduous negotiations, any one of which

might have ended in disaster if it had not been for the goodwill of the General Medical Council and various official and non-official well-wishers in India, and the breakdown, now it has come, is all the more regrettable for that reason. It is difficult, in fact, to regard this deadlock with equanimity, in view of the quite hopeful prospect that an All-India Medical Council, which will be acceptable to the British council may be created within the next few months. Already some evil fruits of the rupture can be seen. In the January number of the *Calcutta Medical Journal* the editor, Dr. B. C. Roy (who holds the M.R.C.P. Lond. and F.R.C.S. Eng., and is a member of the Bengal Legislative Council) suggests retaliation, and comments with satisfaction on the situation which has now arisen. The withdrawal of recognition, and the difficulty of getting into the colleges in England, have already, he says, led a large number of Indians to go to continental Europe. They will come back enamoured of continental instruments and appliances. India imports some two crores worth of stores of this kind. Can we not, he asked, withdraw our orders on British firms so long as the present attitude continues.

Bombay.

In Bombay, also, and doubtless elsewhere, the same spirit is manifest. In the Bombay Legislative Council an eminent physician recently tabled a motion for adjournment of the House to discuss the situation which had arisen owing to the decision of the General Medical Council, and one member remarked that there could only be one answer to the challenge: that was to call upon all students to give up any intention of proceeding to British universities and to urge the Secretary of State not to insist on British qualifications in future. Here, again, strong feeling was shown, and the motion was carried in spite of Government opposition. Another able and highly qualified medical man, who is head of the King Edward Memorial Hospital and associated medical college in Bombay, has spoken still more forcefully. He wishes the Government of India to issue orders against the recruitment for the medical services of the country of persons holding British qualifications only, and calls for other energetic retaliatory measures. Some of this talk is no doubt beside the mark, but some of the material results may be of a permanent nature. Meantime, as was pointed out in the Bombay Legislative Council, newly qualified Indians will be debarred from practising or prosecuting their studies further in Britain, and no Indian will be eligible for a commission in the I.M.S. unless he qualifies for registration in Britain—surely a remarkable introduction to dominion status.

Abortive Efforts at Compromise.

The universities which are concerned in this question of recognition fall into two categories. Bombay, Calcutta, Lucknow and Madras, and the Punjab University, have previously been recognised, while the comparatively new institutions of Patna and Rangoon have never been accepted for registration. Recognition of new schools is a matter requiring careful consideration, but in the case of those already recognised it seems to many inside and outside India unfortunate that the Council has not felt justified, in view of the very important interests involved—and even, perhaps, having some regard to the present difficult political situation—in tiding over this crisis without resorting to extreme measures. The correspondence laid on the table of the Assembly on March 20th shows that the Indian Government, although they had been favourably disposed to the proposal, eventually were forced to the conclusion that the appointment of the Commissioner of Medical Qualifications suggested by the British council was out of the question, owing to the strong opposition manifested both in the Assembly and outside it, and therefore put forward an alternative scheme, framed by a conference of universities,

for the creation of a very authoritative board, consisting of representatives of the Government of India and the medical faculties, as a temporary measure, for determining and supervising medical qualifications and standards. The board was to have as president the Director-General of the Indian Medical Service, and was to appoint three inspectors, specialists in their own subjects (medicine, surgery, and midwifery), who would have reported to the board, which would then have decided whether a guarantee should or should not have been given to the British council as to whether the medical degrees concerned implied the minimum qualifications accepted for registration in Great Britain. It is possible to realise the difficulties under which the General Medical Council has laboured in dealing with India, and the captious nature of much of the comment which has been levelled at the Council by Indian critics, and yet to regret that on this occasion the Council did not exercise a little more patience, in view of the gravity of the issues involved, and the efforts which have already been made, in many quarters, to meet their requirements. Buildings have been enlarged, equipment improved, the curriculum revised (very much on the lines desired by the Council), clinical facilities have been extended, and the numbers of students, which had become excessive during and after the war, reduced to reasonable proportions. If all this is taken into consideration it does not appear that any great risk would have been run by continuing recognition provisionally, to meet a critical situation such as the present.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Medical Economics.

Mr. M. M. Davis, director for medical services of the Julius Rosenwald Fund and a well-known economist, computes that the actual outlay of the American public because of sickness is not far short of 3,000,000,000 dollars. This is exclusive of the cost of the sickness in lost time, disability, and premature death, which items would quadruple the bill. Three billion dollars is a large sum, but is less than the sum spent yearly on tobacco and sweets. Of the total he estimates that \$625,000,000 is paid to private practitioners, whose average gross income is \$1500. More money is spent on drugs and appliances than is paid in fees. It has been estimated on good authority that at least two-thirds of the money spent in this way is wasted. That much of the necessary expenditure can be cut down by preventive medicine is shown by the fact that there are still 150,000 cases of typhoid fever each year, costing in sickness bills and loss of wages not less than \$35,000,000. But it is not really the amount of the sickness bill so much as the distribution of its burden which gives rise to complaint. About half of the total burden falls upon a sixth of the population. Moreover, doctors' bills are usually the most unexpected and least provided for. Instalment payments are a partial solution. Many banks now make arrangements to accept undertakings for monthly payment of bills and credit the whole to the physician at a discount which pays them for the trouble and risk of collection. Private and mutual insurance companies are also helping to some extent to spread the burden of payment more evenly.

Commonwealth Fund Report.

The annual report of the Commonwealth Fund announces an interesting departure in policy. Grants are to be made available for the establishment of general hospitals in rural sections of the country where at present medical aid can only be obtained, if at all, from a considerable distance. Scholarships are to be provided for medical students who intend

Diathermy used with a fine tool is very useful for severing the vessels that enter the capsule as the tonsil is being dislocated during the dissection.

I am, Sir, yours faithfully,

C. HAMBLETON THOMAS, F.R.C.S.

Harley-street, W., April 23rd, 1930.

THE STETHOSCOPE IN THE DIAGNOSIS OF PULMONARY TUBERCULOSIS.

To the Editor of the LANCET.

SIR,—In the LANCET of April 19th (p. 872) there is a reference to some remarks by Dr. J. Gravesen, of Vejle fjord, on the lack of usefulness of the stethoscope in the diagnosing of pulmonary tuberculosis. All sanatorium physicians of experience must have been aware of this for some years; indeed, the more attempts which have been made to establish a diagnosis of this condition without the consideration of symptoms the later has the disease been discovered, and such methods as looking for tubercle bacilli, though still insisted on in some quarters, are really a policy of despair. Even the X ray method is not reliable, as was recently shown by Dr. F. G. Chandler in your own columns,¹ where he tells us of a case with hæmoptysis together with the finding of tubercle bacilli in the sputum in which the X ray picture was normal. It should be remembered that there are X ray pictures and X ray pictures; there are also interpretations and interpretations of the same, with the result that a patient may be put to both unnecessary expense and unnecessary danger through having to leave his bed when he may be suffering from symptoms indicating activity of disease, perhaps to travel a considerable distance and at the end to be told (quite incorrectly) that he has nothing the matter with him, although he himself is feeling desperately ill. The advantage of considering symptoms is that by their means it may be possible to come to a diagnosis; at the same time it is from symptoms that we are able to decide, whatever the physical findings may be, the urgency or otherwise of treatment. A rectal temperature measurement is a great assistance in diagnosis and essential for treatment. When there are few physical signs combined with symptoms of toxæmia then the prognosis is grave.

I have no doubt that pulmonary tuberculosis has changed very considerably in the last 30 years. As a serious affection it seems to be dying out. In Ayrshire the number of deaths registered in one year as due to pulmonary tuberculosis has fallen to 126 out of a population of 300,000. As we admit to this sanatorium about 220 cases a year and have other beds elsewhere to the number of about 60, it would appear that the disease is well in hand. Nevertheless, at the present moment I have a waiting list of about 30.

I am, Sir, yours faithfully,

EDWARD E. PREST.

Ayrshire Sanatorium, New Cumnock, April 26th, 1930.

¹ THE LANCET, March 15th, p. 588.

BRADFORD ROYAL INFIRMARY.—In 1929 there were 7953 casualty patients, and 49,712 treatments in the massage and remedial exercises department, an increase of more than 4000. The average weekly cost of each in-patient (3845) was £2 15s. 1d., a merely fractional increase. They stayed on the average 22.5 days.

LANDSCAPES IN A HOSPITAL WARD.—An extension of Kingston-on-Thames Victoria Hospital was opened recently by Mrs. Leonard Bentall, whose husband has contributed extensively to the work, which has cost £13,000. The enlargements include a children's ward of nine cots—children have hitherto occupied adult wards—and nine private wards (10 beds), for paying patients. The walls and ceiling of the children's ward are painted with landscapes combining water, hills, and woodlands—a decoration which is said to be unique in an English hospital.

Obituary.

FREDERICK EDWARD WYNNE, B.A., M.B. DUB., D.P.H.

Dr. F. E. Wynne, whose death on April 22nd was recorded in our last issue, had only been ill for a few days, and his death at 50 years of age cuts short a career of unusual value in the service of public health.

Frederick Wynne was born at Kilkenny in 1870, fourth son of the Rt. Rev. F. R. Wynne, D.D., Bishop of Killaloe, and followed his elder brother, John Darley, to Trinity College, Dublin, where both graduated in arts and medicine, the younger in 1891. His course was distinguished, for he took the Hudson scholarship and was gold medallist at Adelaide Hospital, where he later served for a time as resident officer, and he was hon.

secretary of the University Biological Society. After further experience at the Rotunda Hospital he migrated in 1896 to Leigh, in Lancashire, where he started in practice and held the position of hon. surgeon to the local infirmary. General practice obviously did not give him the scope he desired, for from his student days he was a fluent and persuasive speaker, of great versatility in debate,

DR. F. E. WYNNE.

[Photograph by Lafayette.]

and he began to be conscious of gifts of propaganda and organisation which would have readier outlet in public service. In 1900 he was appointed first full-time medical officer for Leigh, and three years later went on to Wigan, where he remained throughout the period of the war until in 1921 the opportunity offered of succeeding Dr. Scurfield as medical officer of health for Sheffield. At Wigan he combined the duties of medical officer of health, tuberculosis officer, chief school medical officer, and superintendent of the infectious diseases hospital, and when he left he was engaged in establishing a further hospital of 72 beds for the treatment of tuberculosis. It was at his instigation that the Wigan Corporation maintained its own herd of milch kine. As soon as war broke out in 1914 Dr. Wynne obtained a commission in the R.A.M.C., and was detailed for service in Egypt, where he became divisional sanitary officer to the Expeditionary Force.

For the remaining nine years of his life he impressed his personality on the sanitary services of Sheffield. Open-air life and freedom to breathe and live properly never had a stronger advocate. Schemes of clearance and rehousing always had his warm support, and his interest extended to such minutiae as the paving of yards and courts, and to the small amenities which determine the hygienic life of a community. His name soon became well known in the city, for he was not only frank and outspoken but wilfully put

his teaching into provocative form and revelled in the appearance of heterodoxy. At regular intervals he hurled what he called medical bombshells which continued to crackle for weeks at a time in the columns of the local press. He was equally uncompromising in professional circles, as in an address given at Glasgow in 1922 when he supported the thesis that the tax- and rate-payer is being bled by expenditure which produces no adequate return in improved health and prolonged life. In the following year at Hull he asked: "Should infant mortality be reduced?" not mincing words in condemning sentimental propaganda in favour of unlimited production of babies. Nevertheless he concluded with the admission that a reduced rate of infant mortality may itself prove a factor in bringing about the desired reduction in the birth-rate. No doubt his public work was coloured by his views on democracy, for, though geniality and kindness itself in all personal relations, he was an aristocrat at heart, and held to the paramount value of heredity and the permanence of sound gerin-plasm.

Wynne's literary urge took him early, for when barely qualified he contributed "The Blacklegs of the Jerry Pit" to *Chapman's Magazine*, soon followed by "A Conversion and Its Sequel." While still at Leigh he wrote his first two novels, "Faith Unfaithful" and "Fortune's Fool"; a play called "Subsidence," full of local colour, was produced at the Gaiety Theatre in Manchester. "Mediterranean Mystery" was perhaps his best work of fiction, but "Digby's Miracle," which appeared in 1924, could only have been written by a medical man, for it tells of a village practitioner, by training and inclination an experimental physiologist, whose special knowledge finds limited scope until it enables him to organise a miracle by restoring sight to an hysterical girl through the curative waters of an old well. His easy exposition found play in a scholarly little book on "Ductless and Other Glands," embodying the results of endocrine research, and recording his own view that old age might be as physiological a period as any other, and probably no less pleasant, if youth and maturity were rightly used. He wrote many articles on public health subjects for the press, and was for many years a medical correspondent of the *Manchester Guardian*.

Dr. Wynne held many offices. He was professor of public health in the University of Sheffield, a member of the Senate, and presided for some time over the north-western section of the Society of Medical Officers of Health. Only recently he laid down the position of hon. pathologist and bacteriologist to the Wigan Infirmary.

He leaves a widow and three sons.

SHEFFIELD ROYAL INFIRMARY.—The annual report states that the annual cost per patient in 1929 was £17 6s. 2d., an increase of £0 3s., but at £0 11s. 7d. the cost of each in-patient fell by 11s. 1d. Out-patients cost 1s. 6d. each, a reduction of 7d. In the Godfrey Walker convalescent home each in-patient cost £81 15s. 2d., an increase of £1 10s. 3d. Close co-operation between the Sheffield municipal and voluntary hospitals has been assured by the creation of a joint advisory committee composed of lay and medical representatives of each.

DONATIONS AND BEQUESTS.—Mrs. Sophia Longley, of Lydhurst-avenue, Streatham-hill, S.W., left £500 each to Guy's Hospital, St. Thomas's Hospital, and St. Bartholomew's Hospital.—Mr. George Brident of Yew Tree House, Ombersley, Worcestershire, left 1000 guineas each to Middlesex Hospital and the Worcester Infirmary.—Mr. J. F. W. Deacon, J.P., hon. treasurer of the London Lock Hospital and Home, has made a donation of £500 to its funds, and The Worshipful Company of Goldsmiths had made a grant of £200 to this institution. The following legacies have been bequeathed to the institution: £1000 from the late Mr. George Toller, and £10 from the late Mr. Henry Kruger, of Liverpool.—Sir William Milligan, M.D., LL.D., of Westbourne, Rusholme, Manchester, who left unsettled property of the value of £293,470, bequeathed his medical library to the University of Aberdeen.

Medical News.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—At an ordinary quarterly Committee of the College held on April 21th, with Sir John Rose Bradford, the president, in the chair, the following members of the College were elected to the Fellowship:—

Ralph Henry Crowley, Charles Hunter, Leonard George Joseph Mackey, Edward Burton Cusson, William Mason Jameson, Arthur John Scott Pinchin, Adolphus Alrahams, Alan Worsley Holmes & Court, Thomas Archibald Malloch, Arthur Percgrine Thomson, Graham Selby Wilson, Henry Wallace Jones, James Calvert Spence, William Brown, Joseph Edmund Clark-Kennedy, Hugh Reginald Dutton, James Purlton Martin, Macdonald Critchley, and Arthur Salisbury MacNalty.

The following were nominated by the Council under By-law XXXVIII (b):—

Walter Ernest Dixon, John James Rickard Macleod.

The following candidates were admitted Members of the College:—

Anthony Dominic Abdullah, Edward William Anderson, Lennox Gordon Bell, Charles Allan Birch, Edward John Cronin, John Nathaniel Cumings, Amar Nath Duggal, John Lawrence Howland Easton, Phyllis Victoria Lillia Epps, Florence Margaret Gamble, Stanley Jack Hartfall, Albert Joseph Haydon, Mary Victoria Alexander, Thomas Alfred Hunter, Simon Kim, Isabella Louise Hamilton Livingstone, Muriel Mackenzie, Lucy Margaret Theodora Masterman, Swithin Pinder Meadows, Thomas Morton, George White Pickering, Max Michael Posel, Charles Frank Seaton, William Arklay Steel, Arthur Goronwy Watkins, and Henry Yellowless.

Sir John Rose Bradford was appointed to represent the College at the Jubilee Celebrations at the University of Manchester on May 23rd.—By a resolution of the College the President was asked to convey a vote of condolence to the family of the late Poet Laureate, Robert Bridges, O.M., who was a Fellow of the College.

It was reported that with the concurrence of the President the Medical Department of the Admiralty have awarded the Gilbert Blane Gold Medal for 1930 to Surg.-Lieut. Commander J. F. H. Gausson.

Dr. R. A. Young was appointed Representative of the College at the Sixteenth Annual Congress of the National Association for the Prevention of Tuberculosis to be held July 3rd to 8th.—Dr. William Hunter was appointed to represent the College on a Committee of the People's League of Health to consider the Cause and Eradication of Bovine Tuberculosis.

Licences to practise were conferred upon 143 candidates (121 men and 18 women) who have passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board and have complied with the by-laws of the College. The following are the names and medical schools of the successful candidates:—

M. Ata Ullah, Punjab and Charing Cross; H. B. Bagshaw, Cambridge and London; G. N. Bailey, Cambridge and St. Thomas's; A. H. Baker, Manchester; J. E. G. Baker, London; A. N. Barker and F. Bartholomew, St. Thomas's; G. R. Bashford, Birmingham; D. A. Beattie, St. Bart's; D. H. Bolton, St. Thomas's; A. E. Bowling, Leeds; Mabel Brewster, Royal Free; R. G. Brooks, Manchester; C. C. Brown, Cambridge and Middlesex; A. Buchanan, Univ. Coll. C; E. Burridge, Birmingham; G. G. Cameron, Guy's; S. N. Chopra, Punjab, Edinburgh, and Middlesex; D. S. Chowdhury, Punjab and London; J. F. Coates, Bristol; A. F. H. Coke, Guy's; Charles A. G. Conway, Royal Free; J. H. Conway, Cambridge and St. Thomas's; Margaret E. Cook, Royal Free; H. Coorland, St. Bart's; H. D. Cronyn, St. Mary's; H. Curtis, Cambridge and St. Thomas's; A. L. d'Abreu, Birmingham; C. M. Dell, St. Thomas's; D. H. D. Edwards, Guy's; P. G. Dowdell, Univ. Coll. C; J. C. E. Duggan, Toronto; J. J. Egan, Madras and Birmingham; R. E. M. Favcett, St. Bart's; Sheila J. Ferguson, King's Coll.; F. H. H. Finlaison, R. H. Fish, and E. D. Forster, Cambridge and St. Thomas's; E. T. Frederick, St. Bart's; J. D. J. Freeman, St. Thomas's; W. W. Gerrard, Liverpool; P. R. Graves, St. Thomas's; S. R. Gnewardene, Ceylon and Univ. Coll. C; H. C. Haile, Madras and St. Mary's; C. H. Hamilton, Cambridge and Liverpool; D. H. Hay, Cambridge and St. Bart's; Geraldine M. J. D. Kercher, Manchester; Columbia M. D. Heathcote, Charing Cross; J. Henry, Leeds; J. R. Hindmarsh, Durham; Cicely L. Hughton and S. W. Holmes, St. Mary's; Ethel E. Hopper, Charing Cross and Westminster; D. H. H. Irvine, Oxford and St. Thomas's; D. Ivey, Guy's; L. A. Jacob, Madras and St. Thomas's; M. M. St. G. Johnstone, Cambridge and St. Thomas's; E. G. M. Jones, Univ. Coll. C; J. K. Kaur, St. Thomas's; C. K. Kapila, Bangalore and Charing Cross; F. H. K. Kaur, St. Bart's; J. D. Kershaw, Univ. Coll. C; S. Lal, Punjab and Middlesex; R. F. L. Lander, Middlesex; Grace Law, King's Coll.; F. H. Leaver, St. Bart's; E. Z. Levy, Manchester; G. S. H. Little, St. Bart's; J. P. Lloyd, London; H. L. Lwov, Vienna and St. George's; H. G. McComas, Guy's; S. McDonald, Cambridge and Durham; W. McKissock, St. George's;

R. W. Malim, Cambridge and St. Thomas's; Margery L. Maltby, Royal Free; M. Mandelstam, Oxford and St. Bart's; R. S. Mann, Cambridge and Univ. Coll.; C. E. P. Markby, Cambridge and St. Thomas's; J. H. G. Mason, Middlesex; C. B. Melville, Melbourne and Guy's; J. B. S. Morgan, Cardiff and St. Bart's; F. Murray, London; F. J. Napier, Guy's; Alonzo M. Nodine and A. M. Nussbrecher, Middlesex; R. Nutt, Oxford and St. Thomas's; C. L. Oakley, Univ. Coll.; G. L. Ormerod, Cambridge and St. Thomas's; M. Owen, Cardiff and Univ. Coll.; P. M. Oxley, St. Bart's; C. H. Pauli, Bristol; D. D. Payne, St. Thomas's; M. Phillips, London; F. E. Pilkington, Cambridge and King's Coll.; J. R. F. Popplewell, Guy's; J. O. Poynton, Cambridge and Charing Cross; A. C. Price, Guy's; S. Ramadas, Bombay and St. George's; S. Ramanathan, Ceylon and King's Coll.; G. E. Ranawake, Ceylon and Middlesex; J. M. Reese, St. Mary's; J. I. Rennie and A. H. T. Robb-Smith, St. Bart's; H. E. W. Robertson, Cambridge and St. Bart's; C. G. Roberts, Cambridge and Westminster; Victoria M. Robinson, Oxford and King's Coll.; J. D. Rose, Durham; Pattie E. Rose, Royal Free and St. Mary's; K. M. Ross, St. Bart's; C. A. Rumball, Guy's; J. Sakula, Middlesex; K. T. Samatapala, Ceylon and King's Coll.; S. Scher, Cape and Univ. Coll.; L. Seaton, Leeds; K. M. Seedat, Bombay and Charing Cross; M. H. Shah, Punjab and Univ. Coll.; Ursula Shelley, Royal Free; Edna F. Sheridan, King's Coll.; L. Silman and S. Silman, Leeds; Phyllis F. L. Simon, Royal Free; J. G. Sleigh, Cambridge and King's Coll.; Edith M. P. Smith, Cambridge and Charing Cross; P. Somasunder, Madras and London; B. Southwell, Guy's; G. H. G. Southwell-Sander, Cambridge and St. Thomas's; T. M. Spilhaus, St. Thomas's; J. K. Stanger, Durham; R. W. Stephenson, Guy's; B. P. Sur, Calcutta and Edinburgh; F. H. Taylor, Durham; G. Taylor, Manchester; J. N. Vasudeva, Punjab and St. Thomas's; L. H. Wharton, Bristol; J. C. G. Whitelaw, Cambridge and St. Thomas's; D. A. Williams, Cardiff and Univ. Coll.; Rose E. Williams, Royal Free; F. S. Winton, Cambridge and St. George's; Joyce R. Woods, Royal Free; G. R. H. Wrangham, St. Mary's; and W. Young, Cardiff and St. Mary's.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates were successful:

Surgery.—R. P. Davies, Cardiff and London Hosp.; M. Halperine, Paris and London Hosp.; J. E. R. Heppollette and G. G. Muller, St. Mary's Hosp.; E. G. Nair, Manchester; and L. J. Pearson, Birmingham.
Medicine.—J. Britanski, London Hosp.
Forensic Medicine.—J. S. Bury, Manchester; H. Glynn, Charing Cross Hosp.; J. M. L. Love, St. Mary's Hosp.; and A. W. B. Wiggins, Sheffield.
Midwifery.—E. C. Dymond and C. Seeley, St. Mary's Hosp.; G. R. Germany, Sheffield; E. G. Nair, Manchester; and G. Wilsker, Leicce and Royal Free Hosp.
 The Diploma of the Society was granted to the following candidates, entitling them to practise Medicine, Surgery, and Midwifery:—J. S. Bury, E. G. Nair, and L. J. Pearson.

UNIVERSITY OF LONDON.—At recent examinations the following candidates were successful:—

D.P.M.

With Special Knowledge of Mental Deficiency.—C. J. C. Earl.
With Special Knowledge of Psychiatry.—Beryl Senneck.

University College.—The six lectures on Special Sense Physiology, to be given by Dr. R. J. Lythgoe, will be at 5 P.M. on May 15th, 20th, 22nd, 27th, and 29th, and on June 3rd. Those by Prof. F. G. Cole, F.R.S., on the Early History of Generation and Comparative Anatomy will be at 5.30 P.M. on May 7th, 8th, 14th, 16th, 21st, and 22nd. Dr. W. E. Blatz, assistant professor of psychology in the University of Toronto, will deliver a lecture on Modern Theories in Habit Training in the Pre-School Child, on Tuesday, May 13th, at 5.30 P.M.

BRITISH INSTITUTE OF RADIOLOGY.—The annual general meeting of this institute (incorporated with the Röntgen Society) will be held at 32, Welbeck-street, London, W., at 8.30 P.M., on Thursday, May 15th. Dr. Peter Kerley will read a paper on the Pathology of Early Pulmonary Tuberculosis as revealed by X rays. On the following morning provincial members are invited to visit the Westminster Hospital Annexe (Radium) 66, Fitzjohn's-avenue, Hampstead, N.W.

LONDON AND COUNTIES MEDICAL PROTECTION SOCIETY.—The annual general meeting of this Society was held at Victory House, Leicester-square, on Wednesday last, April 30th, Sir John Rose Bradford, the president of the Society, being in the chair. In moving the reception of the annual report Sir John pointed to the increasing adherence of the profession to the Society, nearly a thousand new members having been elected during the year, while the large sums of money paid in defending and maintaining the interests of the members was proving the absolute necessity of organisation for protecting medical men from many of the risks associated with professional life. The annual report, statement of accounts, and balance sheet having been received and adopted, the president and the principal officers were unanimously re-elected for the ensuing year.

NAVAL MEDICAL COMPASSIONATE FUND.—At the quarterly meeting of the Directors of this Fund on April 24th the sum of £180 was distributed among the several applicants.

SOCIETY OF RADIOGRAPHERS.—At a meeting of this society to be held at 32, Welbeck-street, London, W., at 7 P.M. on Wednesday, May 14th, Mr. O. H. Holbeach will read a paper on the Planning of an X Ray Department.

INVALID CHILDREN'S AID ASSOCIATION.—The annual meeting of this association will be held at 18, Carlton House Terrace, on Tuesday, May 6th, at 3 P.M., with Viscount Goschen in the chair. Among the speakers will be Dr. F. E. Fremantle, M.P., and Sir Charters Symonds. Admission is by ticket only, and the Secretary's address is 117, Piccadilly, W. 1.

RETIREMENT OF MR. E. W. MORRIS.—It is announced that Mr. E. W. Morris, House Governor of the London Hospital, will retire from that position in July next. Mr. Morris, who has been House Governor since 1903, is the author of "A History of the London Hospital."

WALSALL ISOLATION HOSPITAL.—The Mayor of Walsall has formally opened the first portion of a new isolation hospital for the county borough at Goscote, a short distance from the town. The building, which is to cost £30,000, contains a block of 34 beds for scarlet fever and diphtheria, and a block of ten beds for mixed isolation cases. There will eventually be 100 beds.

CONTRIBUTORY SCHEMES IN YORKSHIRE.—The Yorkshire voluntary hospitals committee has approved of a proposal that every hospital in the county should have a scheme of regular contributions, framed according to the conditions of the district, patients to be entitled to full privileges in any hospital, irrespective of whether it is that to which they contribute.

NORFOLK AND NORWICH HOSPITAL.—Since the war the number of beds has been nearly doubled, and several additions have been made to specialist departments, but the accommodation for a greatly increased nursing staff has not been increased for nearly 30 years. Unless the accommodation is augmented it will be impossible to provide nurses for the new eye, ear and throat ward now being erected. It has, therefore, been decided to appeal for £10,000 for the extension of the nurses' home. The people of Norfolk subscribe to the hospital at the rate of nearly two shillings per head of the entire population.

HOSPITAL ACCOMMODATION AT PLYMOUTH.—Mr. Arthur Greenwood, the Minister of Health, on April 12th, laid the foundation-stone of an extension of the Plymouth Mental Hospital at Blackdon, and of new nurses' quarters at Swilly Hospital. The work at Blackdon is part of a scheme of extension which, when completed, will cost £129,000 and accommodate 839 patients. At present the mental hospital, which contains an average of 515 patients, is overcrowded to the extent of 70 patients, while a further 162 are boarded out.

PRINCESS ALICE HOSPITAL, EASTBOURNE.—At the annual meeting of this hospital it was stated that although there had been another big increase in the number of in-patients, the governors thought it inadvisable to venture on any scheme of enlargement until time had elapsed in which to gain experience of the working of the Local Government Act. This also applied to a contributory scheme and nurses' superannuation. The year's finances showed an increase of ordinary expenditure over ordinary income of £993, despite great attention to economy. The governors decided that legacies should not, in future, be consumed in paying off deficit, but invested to provide an annual income.

THE NEW SUSSEX HOSPITAL.—A year of steady growth and improvement was reported at the annual meeting on April 2nd of the New Sussex Hospital for Women and Children at Brighton. The 12 months' working marked a deficit of £214, and a total overdraft (including this sum) of £614 at the bank; but it was pointed out that but for the adoption of the federated superannuation scheme for nurses, and the trebling of the rate demand under the new assessment, the expenses would have been met. A special appeal is to be launched to meet the deficit; also for a considerable sum to cover urgent repairs. During 1929 a new wing was in full occupation, an additional department had been opened, and the number of patients set up a fresh record. The demands upon the out-patient, X ray and massage departments, and the dispensary, were far in excess of the accommodation, and the governors, it was stated, were considering plans for the necessary extension. The hospital is staffed by medical women.

LEAGUE FOR SEXUAL REFORM.—The fourth congress of the World League for Sexual Reform on a Scientific Basis will be held at Vienna from Sept. 13th to 20th.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—The annual provincial meeting will be held at Harrogate at 4 P.M. on May 10th, when a discussion will be held on Rheumatism in its Public Health Aspects. In the evening the members will be entertained at dinner by the Mayor and Corporation. Those who intend to be present are asked to notify the Executive Secretary at 1, Upper Montague-street, W.C.1, at once.

NATIVE PRACTITIONER IN DURBAN.—A Natal correspondent informs us that Dr. I. B. Gumede, who has graduated at Birmingham and has returned to practise in South Africa, is the first practitioner that the natives of Natal and Zululand have produced since the death of Dr. Nembula, over 30 years ago. Before coming to England he was educated at the South African Native College at Fort Hare, Cape Province.

A LONDON HOSPITAL SHELTER.—An ornamental shelter erected over the paths in the main quadrangle of the London Hospital, at the charge of Sir William Paulin, has formally inaugurated last week. It consists of teak columns and beams supporting a copper-covered roof, and provides a sheltered way from the wards to the nurses' quarters. The local authorities made it a condition that means must be devised to admit a fire-engine or fire-escape, and the roof is therefore made to open in bascule fashion.

HOSPITAL FIRES.—The central wing of Antrim Mental Hospital (600 patients) has been almost completely destroyed by a fire which began at 10 o'clock at night and is supposed to have been caused by an overheated kitchen flue. Wards nearest to those of the fire contained 300 patients, who had to be removed, together with 60 infirm inmates, to the dining hall, recreation hall, and much of the domestic quarters were gutted, and the damage is estimated at £50,000.—A fire, the origin of which has not been ascertained, broke out in the roof of James Murray's Royal Asylum at Perth, and, although it was localised, much damage was done. Most of the patients were in the grounds, and the 26 who were in the building were removed by Dr. W. D. Chambers, the Medical Superintendent, and the nurses before the arrival of the fire brigade.—The Edward Cox Memorial Cottage Hospital, at Meigle, in Perthshire, was almost entirely destroyed on April 15th by a fire which originated in an attic. There were only three patients, who were safely removed; the caretaker's house, kitchen, and laundry alone were saved. The loss, which is estimated at £20,000, would have been much less serious but for the lack of water, over a mile of hose having to be laid across fields and a main road by the Dundee Fire Brigade to tap Meigle Burn.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

REASSEMBLY AFTER EASTER.

BOTH Houses of Parliament reassembled on Tuesday, April 29th, after the Easter recess.

MINISTRY OF HEALTH VOTE.

On Tuesday, April 29th, the House went into Committee of Supply on the Civil Service estimates. Mr. ROBERT YOUNG was in the chair.

On a vote of £12,721,200 for the salaries and expenses of the Ministry of Health, Mr. A. GREENWOOD (Minister of Health) said that the total amount of the estimate was a little over £2,000,000 less than that for last year. The decrease was accounted for primarily by the discontinuance of certain public health grants as from April 1st this year. Administrative charges showed an increase of £100,000. Dealing with the general housing position the right hon. gentleman said that up to March 31st this year there had been completed since the Armistice in connexion with State-aided schemes of housing 939,000 houses. In addition, private building without Government assistance accounted for 520,000 houses, so that since the end of the war the total number of houses completed in England and Wales amounted to 1,459,000. Of the houses built with State assistance, 527,000 were built by local authorities. Slum clearance had proceeded slowly partly because of the present state of the law, and partly because of the legal decision given in the courts some little time ago, reinforced by another decision given quite recently, and the Housing Bill now before Parliament would meet that situation.

Since the war the State had expended, up to the end of March this year, £85,000,000 on housing. Referring to the progress of town-planning, Mr. Greenwood said that there were now 80 regional planning committees, 60 of which were advisory and 20 executive. Substantial progress had been made in town-planning in the course of the year. At present town-planning schemes were in operation, or proposed, covering in England and Wales at March 31st this year over 5,117,000 acres compared with 1,450,000 acres a year ago. Dealing with the transfer of functions under the new Local Government Act, the right hon. gentleman said that a number of local authorities had straight away appropriated individual institutions for the purposes of the Public Health Acts, and in such cases these institutions would cease to be poor-law institutions and would come under the administration of the committee of the council concerned with the special services for which this scheme was established. But if the council wished to supplement it by the use of other poor-law accommodation, it could do so. This process of appropriating institutions, he imagined, would develop in course of time. Forty-eight out of 62 counties and 75 out of 83 county boroughs had preferred to set up an ad hoc committee as a separate public assistance committee. Forty-two county schemes and 52 county borough schemes provided for the inclusion of co-opted members. It was gratifying to know that 16 county councils and 49 county boroughs had found it possible to make an immediate declaration on their schemes that certain poor-law services for which parallel provision had been made under special Acts of Parliament should be treated exclusively under those Acts and not by way of poor-law relief. One hoped that as the new authorities became more familiar with their work the process of taking services out of the poor-law and operating them under separate Acts would be developed. He had given a good deal of thought to the problem of out-relief and came to the conclusion that the Relief Regulation Order of 1911 required very drastic amendment if it was to be brought into any kind of relation with existing industrial conditions. The Relief Regulation Order, 1930, represented a substantial departure from the previous Order. The two principal changes were, first, that institutional relief was no longer to be regarded as the appropriate form of relief for the able-bodied. The second change had been to suggest that the conditions to the grant of relief should not have as their object merely a deterrent to the destitute person, but should be designed to maintain his morale and physique.

Increase in Sickness Claims.

He (Mr. Greenwood) gathered from what had been said in the press that there was a good deal of anxiety in the minds of hon. Members in regard to the increase of sickness claims under the National Health Insurance Act. The problem was, of course, a very serious one and had been occupying the mind of the Ministry of Health for some time. Two years ago the National Health Insurance Joint Committee authorised the Government Actuary to make an investigation into the substantial increase in recent years in claims for sickness and disability benefits. The Report of the Government Actuary was now in the hands of the Committee. In the meantime the department had been doing what it could in consultation with the approved societies to improve the supervision of claims and the selection of cases for reference to the regional medical officers. In 1928 there was a fall in the number of sickness claims from 1927, but in 1929, even after discounting the serious cases of influenza, there was a considerable rise over 1928. This year for the first three months there was an appreciable reduction, due primarily to the milder weather compared with last year, and the absence of an influenza epidemic. It was quite clear that further examination must take place into the problem. Suggestions have been made that there should be a Departmental Committee, but in his view such a committee would not be the proper body to deal with what was essentially a problem of administration. On the receipt of the report of the Government Actuary the National Insurance Joint Committee decided to extend the scope of the investigations and the whole question was now under the close attention of the officers, administrative and medical, of the insurance departments in all parts of the United Kingdom—England, Wales, and Northern Ireland. When their investigations had proceeded sufficiently far the approved societies would be brought into consultation, as would be the Insurance Acts Committee of the British Medical Association, and out of their investigations and deliberations he hoped that they might get some clearer opinion on what lay behind this very large increase in claims for benefit. He was convinced that there was no simple explanation of the increase. Precisely the same problem was arising in other countries which had fairly well-developed schemes of sickness insurance. In Germany, for example, the increase between 1927 and 1929 was 70 per cent. He did not wish to speak

Notes, Comments, and Abstracts.

SHOULD MEDICINE BE A MENDICANT?

A REVIEW OF OUR HOSPITAL SERVICE.

Harveian Lecture delivered at the Harveian Society of London on March 13th

By ERNEST W. HEY GROVES, F.R.C.S. Eng.,

PROFESSOR OF SURGERY IN THE UNIVERSITY OF BRISTOL.

MORE than 320 years have passed since William Harvey was appointed to be the assistant physician and shortly afterwards to be the full physician in St. Bartholomew's Hospital. It was on Oct. 14th, 1609, that he accepted a charge which enjoined him to attend the hospital at least one day a week, to take no gift or reward of any of the poor, and to be answerable to God as a faithful physician. We are tempted to wonder what this great scholar and gentleman would think if he could revisit his old hospital to-day.

What William Harvey would Think.

He would find a great light shining from its roof to attract men's gaze, a great cry for money to pay for the buildings, whilst papers and hoardings proclaim the same desperate need for financial help. We can almost hear him saying: "In God's name what has happened to this England and to my most revered hospital? Are there so many more poor than there used to be—or have the benefactions of the rich been stolen or diverted?" We should have to say that, on the contrary, the poor as they were known in 1600 hardly exist to-day, and that the people of England were never so rich and give more to hospitals than was paid in those days for all the national revenue.

We may now discuss whether it is well that all our great hospitals, even including that venerable, ancient, and dignified institution founded by Rahere, should be forced into the position of a needy mendicant asking for alms.

The provision and organisation of a perfect hospital and a perfect hospital system has come to be the great aim and ideal of everyone interested in medical practice, science, or education. To have a perfect hospital and to be one working unit in this perfect thing is, or ought to be the secret, or acknowledged ambition of every medical student and medical practitioner in the country.

If you would interrupt me by pointing out that only a very small proportion of practitioners can belong to hospital staffs, I would welcome your interruption by saying that no matter how isolated and remote the practitioner is, or how engrossed in general practice, yet he ought always to be in real active touch with some hospital, for his own good and for that of his patients. In fact I would go further, and say that remoteness and busy-ness are the most urgent reasons why the practitioner should be in close touch with a hospital where the organised co-operation of his fellow-workers is prepared to give stimulus and help to the seeker and in return asks for a contribution to knowledge and assistance in carrying on work begun in hospital, in the patient's own home.

I say, then, that to the idealist, the hospital we strive for should be a high and holy thing, the very temple of medical truth where we reverently handle the mysteries which have been taught us and earnestly endeavour to search out the secrets of infinite nature, hoping each one of us to serve humanity faithfully, and of having, perhaps, the greatest of rewards in finding some treasure in the storehouse of truth, which we may hand on to those who come after us, to be incorporated by them into the greatest ritual of our religion, which is the service of suffering and the quest of health.

Appealing to Sentiment.

Have I got you into the mood I wanted about our profession and its highest expression of learning, teaching, of research and alleviation of suffering—the hospital? If so, then I am ready to ask the question which forms the title of this address—should medicine be a mendicant?

The old picturesque beggar has almost disappeared from our streets, because by a peculiar irony, that very phase of our civilisation, which has made begging the cherished hobby of the well-to-do has made it illegal for the professional beggar to ply his trade! Even in Italy where but a few years ago begging seemed to be the most popular of vocations, it has now almost disappeared.

Good government and prosperity, and, above all, natural self-respect, have decreed that begging must go—and gone it is. But personal begging is not so remote in this country nor countries in which it still flourishes, so distant that there

is any difficulty in picturing its methods and morals. You are accosted in some quiet street by a slouching figure of a man, who has trailing in his wake a bedraggled woman, clutching in her arms a whining child. In terms it may be of snivelling humility, or it may be of truculent menace, you are invited to contribute to the maintenance of this wandering trio. The mendicant, if he is skilled in his art, suits his tone to his hearer, and pleads that it is for his weary wife and hungry child that he is asking help. They have walked an incredible number of miles, have had nothing to eat for days, and unless the child has costly doctor's care it will not live another day. Our feelings on hearing or trying not to hear this appeal are usually those of instinctive distrust and scepticism, resulting from experience. We feel pretty certain that the man is a lazy ruffian, trading on the pitiful condition of the woman and child that he takes with him, in order to get money by begging rather than by working. But it is so much easier to cut short the unpleasant interview by giving the man the money he asks than to refuse or to investigate—that the money is given and the mendicant is confirmed in his shiftless life. Instinct and reason alike counsel that we should refuse. We know quite well that if no one gave the beggar money he would be forced to work. We know that the money given probably goes in drink, that the baby is hired for the purpose of exciting pity, and in short we know full well that mendicancy is a degraded and a degrading thing. The essential method of begging is to make an appeal to sympathy and sentiment rather than to reason, to press urgency of need, so that there may be no time for inquiry; the usual result of begging is indefinitely to prolong the unhappy conditions which are supposed to be relieved. The great art of successful begging is to extort money from people who do not want to give it, and having done this, to represent the transaction as one of voluntary charity. The whole affair being one dictated by pity and carried out by charity cannot be questioned by reason or scrutinised as if it were a business matter. Having once given your money to the beggar, you have no manner of right to dictate to him how he shall spend it.

Our own British hospital system is dependent upon mendicancy. This applies to the oldest institution and those with the finest tradition for service to the community, and to all the hospitals which are responsible for teaching and research. By a curious misuse of terms these hospitals, so dependent upon the bondage of mendicancy are called the voluntary hospitals. At the very outset of our criticism of the mendicant hospital system we must face the claims so often made on its behalf—that it has been a wonderful success—so much so, that we are told that people are actually proud of it. Well, I can only say it does not take much to make some people proud!

Its Amazing Success.

As a matter of hard cash results we must concede that hospital mendicancy has achieved an amazing record. I find on the authority of Burdett that 25 years ago the voluntary hospitals received just under £2,000,000 (£1,985,810 in 1903), but that now the year's income is over 14 millions (£14,006,585 for 1928), more than a seven-fold increase in a quarter of a century! And this at a time when taxation, imperial and local, was never so high, and in the very country where this taxation is higher than anywhere else in the world! It is only because the mendicant method has grown so insidiously that it is tolerated for a moment by sensible people. If anyone will seriously argue that mendicancy is good, then why not extend it to other services of the country? Can we imagine education, the legal service, or civil service being dependent upon haphazard philanthropy and appeals by advertisement?

We might without risking any immediate calamity make the expenses of Ministers and the salaries of Members of Parliament the subject of the voluntary system. The Home Secretary, Chancellor of the Exchequer, the local Member of Parliament, and all the upkeep of the Houses of Parliament would depend for their income on flag days, Parliament Sundays, or upon the wiles of their publicity agents—what an alluring prospect, and yet it is just that we are doing for the hospital service. I venture to say that whereas the hospital is essential for the welfare of the community and could not be dispensed with for a single day, there are many who would view the prospect of being without a Parliament for a few years with the utmost equanimity.

I am not concerned over much for saving the pockets of the people, who pay taxes because they must, and give to charitable appeals because they like. It is obvious that the British public like sentimental appeals, whether by great men and women in high places, by famous people on the wireless, and by the most expert advertisers in the Press or on the boardings. I feel quite sure that if and when the planet Mars is within easy communication with us, that a charitable appeal will be organised in this country to feed

or to clothe or to doctor the needy Martians, and, of course, the appeal will meet with wonderful success. No! the justification for the mendicant system is not established merely by pointing to the fact that so many millions can be obtained by begging—we have to ask whether the system is efficient at present—is likely to be adequate in the future. Begging for the sick poor may have been the best that could be done in days gone by, but it is manifestly failing to-day to provide what is wanted, and which in other countries is actually being provided by other means.

Increasing Complexity of Hospital Service.

One hundred years ago the hospital problem was a comparatively simple one. The sick poor had to be fed and tended whilst he was ill, he was visited by a doctor and ministered to by a clergyman. It was merely a question of providing enough beds, enough nurses, doctors, and clergy. In fact in those days it was but little more than a money problem. Get the money from the charitable public and spend it on the sick poor, counting all the time on the medical profession to give their services for the good cause. But since that time and almost within the lifetime of the present generation, the problem has become much more complicated. Instead of merely tending the sick man, scientific knowledge has proved that it is often possible to cure him, and generally possible to alleviate his sufferings. It has been discovered that the cause of disease can be found out, and sickness often prevented.

A highly complex service of preventive and curative medicine and surgery has taken the place of the merely palliative system of tending the sick man. So that the fact is quite evident that the size and complexity of the hospital problem have so rapidly grown as to be far beyond the competence of any philanthropy, whether we call it voluntary or mendicant, to support.

The poor-law guardians have always had many beds for the sick and injured, but in recent years they have steadily increased the number of beds and improved the character of their buildings, and have distinguished between the sick poor who required active medical and surgical treatment and those who merely need a shelter and an asylum. In most of our large cities at the present moment there are as many hospital beds provided by the municipal authorities as those under the control of voluntary organisations. Of available beds for the treatment of the sick the voluntary institutions have fallen short by about 50 per cent. of the requirements of the community.

It would not, of course, be a fair representation to say that the voluntary hospitals only do about half the work needed, because in respect to the number of cases treated as in-patients, and in respect of out-patients they are still a long way in advance of the municipal institutions. But the outstanding fact remains that in the mere matter of providing enough hospital beds the voluntary system has failed, so that it can only accomplish one-half of what is wanted.

In regard to the number of beds the challenge and growth of the municipal hospitals is far the gravest indictment of the voluntary system. But it is also manifest that when special scientific discovery has made provision of segregated groups of hospital beds necessary, then the demand for such by the community cannot be met by the voluntary hospitals and the local authority is compelled to provide county or municipal institutions for these purposes. Thus acute specific fevers, and then pulmonary tuberculosis, later surgical tuberculosis and venereal disease have had to be put into special public institutions or provided for by the State. This is merely another instance of the fact that the voluntary system is not equal to meeting the requirements of the community. It cannot do so in the matter of the number of beds, it cannot do so in respect of the requirements of special diseases.

The inadequate provision of beds by the voluntary hospitals is most clearly shown by the very long lists of patients waiting for admission, and the known fact that many of these have to wait weeks before they are admitted. One provincial hospital alone has 3000 patients on its waiting-list. Some of these are patients suffering from malignant disease for whom delay means a loss of what slender chance they have for cure or alleviation, others are working men, who are thrown out of work during all the waiting period. From an economic point of view much more money is spent in supporting these men whilst out of work than would be needed to pay full maintenance fees for them in hospital for three or four weeks. It would probably be an understatement of the facts if we were to say that at the present moment there are 10,000 people waiting for admission to the voluntary hospitals, and that 5000 of these will suffer in money, health, and prospect of recovery from this delay in the treatment of their case. This outstanding fact, that the voluntary hospital system which was competent to meet the needs of the community 30 years ago is now quite inadequate, is due not to any alteration in the economic

situation, or to the increase of the population, or to the greater number of sick people. Actually the income of the voluntary hospitals has by its sevenfold increase far outstripped the increase in population, cost of living, or morbidity.

Two Fundamental Changes.

There have been two fundamental changes in the relationship between the supply and demand of hospital service which not only account for the failure of the voluntary system, but which make it clear that mendicancy is not only inadequate, but also unsuitable and indecent. These two changes have come about so gradually that their importance has been overlooked.

In the first place medical practice, both in regard to diagnosis and treatment, has become so complex that it requires to be carried out in a scientific institution, provided with apparatus and personnel suitable for scientific work. In other words, a sick or injured person will require a properly equipped institution for his recovery. The second change follows naturally from the first. If the care of the sick and injured requires scientific institutions then this need will be equally great for the rich as for the poor, for the self-supporting as well as for the indigent.

This may be illustrated by two common conditions requiring medical or surgical attention. The first is a case of dyspepsia. The patient will require to have his history taken by an experienced practitioner, he will be referred to a biochemist or pathologist to report on the chemical changes of his gastric contents and the presence of occult blood and other changes in the faeces, he must be examined by an expert radiologist to know whether the mobility of the stomach, duodenum, and intestines is normal or abnormal and whether there is any ulcer or growth to be seen; if a removable cause for the dyspepsia is found he will require the services of a gastrologist, a surgeon, and an assistant surgeon to perform the necessary operation, whilst his recovery will depend upon the skill of a house surgeon, a sister, and a nurse. So that this one case needs the services of no less than nine specially trained people whose work will be much more satisfactory if they are accustomed to act together as a well-trained team.

The other instance is that of a man run over in the street and suffering from an infected open fracture. His treatment will require the immediate services of a house surgeon, with one or two dressers, the administration of an anæsthetic, the administration of anti-tetanic and anti-gas sera, the examination of his wound secretion by a pathologist, provided with a laboratory and staff of assistants. Later he will want the help of a surgeon for manipulation or splinting of the fracture, and perhaps he will want a bone-grafting operation, which can only be done with the best chance of success by a specialist who has had adequate experience of this work, and who must be able to rely upon the help of a trained assistant and nurses with special knowledge. Again this means the need of eight or nine highly skilled persons accustomed to work together as a team.

Gravity of Illness, not Poverty.

This I believe to be the crux of the whole problem. The *raison d'être* of the voluntary hospital was the idea of relief of the sick poor. The need of the present hospital system is to provide adequate investigation and treatment of disease for the whole community. It may have been the right and proper thing to accept the rich man's gifts and to supplement these by begging alms to help the sick poor, but by no possible reason can justification be found for making a charity of the application of modern science for the needs of the middle classes or the rich. The total number and relative proportion of the very poor people is much less than it was, but the need for hospital beds is much greater. This is not because people with money wish to become the objects of charity, but because any man, whatever his means, knows quite well, and his doctor tells him that if he is seriously ill he must enter a hospital, so that he shall have the full investigation, nursing, and treatment that can only be provided in a scientific institution. This cardinal fact, that the gravity of the illness or the danger of the injury which the patient suffers and not his poverty constitutes the chief claim he has to admission to a hospital is shown in various ways. The police and the street-ambulance take every serious case of accident straight to the nearest hospital.

In some places, if the patient is a well-to-do man, he is kept for treatment, and a suitable donation to the charity is expected of him, in others he is transferred to a private nursing home as soon as possible. In a very few he is put into a private ward and pays his way, both to hospital and to medical staff. If a man injured in a street motor accident is taken to a nursing home then the expenses of his stay there and all fees for medical attendance become a claim against some insurance company, which is met, generally, without demur. But if the same man is taken to a hospital and receives the same attention, there is no claim either for

maintenance, nursing, or surgical attendance, because the patient is the recipient of charity!

The managers of most voluntary hospitals, partly driven by necessity to raise funds and partly because they know that most of the patients are by no means destitute, have instituted a charge to all their patients of about £1 a week, which is modified or remitted if the patient cannot pay. The voluntary system has indeed changed its character in attempting to carry out a task for which it was never intended, and for which it is quite unfitted. Only a certain portion of the funds can now be described as the product of free-will—the rest is literally extorted from a reluctant and over-taxed population. Most of the patients have to pay a contribution towards their maintenance, and an increasingly large number have their entire maintenance provided by a contributory insurance scheme.

In fact the only element of the original "voluntary" plan which remains in its pristine beauty is that the visiting medical staff still give their services for nothing! As a matter of fact in the old days it was not considered beneath the dignity of the physician to receive a salary for his hospital appointment. Harvey himself accepted £33 6s. 8d. a year for one day's attendance per week. The sum named would be the equivalent of about £100 of our money, and thus visiting members of a hospital staff should, if this old tradition had been maintained, receive about £400 or £500 for attendance on four or five days a week at a hospital.

One of the stock arguments against the municipalisation of hospitals is that this would involve paying the doctors. In the recent report of the Royal Commission, inquiring into the working of the National Health Insurance Act, this very point is discussed. This Act produces each year a large surplus, and it would seem obvious that this might be used to pay hospital charges of insured persons who need institutional treatment. But if this were done then the doctors who now work for nothing would expect to be paid—and that, of course, would be a waste of public money which no Royal Commission could possibly contemplate!

So that we are faced with this rather startling position—that there is an available fund for paying for patients in hospital, but that to pay this money for such a purpose would not be prudent because then public admission would have to be made that most hospital patients are not destitute poor, but the well-cared-for children of a wealthy State, and in addition to their maintenance in hospital, further funds would have to be found to pay the men who are doing the healing work. Why on such lines hospitals might even become self-supporting, and then what would become of the "voluntary system"? Large sums of money would be scandalously wasted in paying a profession that now works without payment, and the poor over-worked publicity agents who organise hospital appeals would be thrown out of their job!

Exploitation of the Medical Profession.

This is a definite part of the mendicant system. It has grown up so gradually that it has hardly been noticed. It has been accompanied by so much unctuous flattery of the profession that very few have cared to raise a protest which would bring in no cash but might rob us of the glamour attaching to noble and disinterested philanthropists. Little more than a generation ago the position of the visiting staff of a hospital entailed but little work and responsibility. A visit to the hospital twice a week involving one or two hours, administering to destitute recipients of charity. Now I suppose it would not be an exaggeration to say that to-day the best type of hospital physician or surgeon spends quite half his working time at the hospital, and frequently is called there at night. He is actually applying the modern discoveries of science to the investigation and treatment of disease, and to the mitigation of those accidents of industrial life and modern travel which the use of machinery has caused. He is doing this for the working men and for their wives and children—for those who form the bulk of the most prosperous nation in Europe. And he is still expected to do this responsible work without any direct fee or reward.

But I should be digressing from my subject if I allowed myself to linger on this topic; the last thing in the world I would wish to do would be to make an ad misericordiam appeal for the indigent consultant—although it would not be difficult to prove that this man is often denied the fair pecuniary reward of his work, such as is accorded to a man of like ability and independence who devotes himself to business pursuits. But it is necessary to point out how this demand that the consultant class should do so much of the essential work of the hospitals gratuitously does act against the best interests of the hospital service itself. It does so by seriously limiting the choice of the best men for the most important work in the medical service of the country. It makes it most difficult for any medical man or woman to aspire to a position of a hospital consultant, unless he or she is possessed of private means. If he has not got money

or cannot marry money, then if he would come on a hospital staff he must for years enslave himself by various methods of making money, such as coaching students, taking various small paid appointments, or ingratiating himself with any general practitioner who is likely to give him private work. All this means that just when he is at his best he must be absorbed in the great problem of making a competency and he cannot devote himself to what ought to be his chief occupation of scientific pursuit. It is only natural, then, that after 10 or 15 years of struggle for existence, when he at last finds himself fairly affluent, he should have lost the zest for research or discovery, and be content to reap the harvest of his toil. We have then the explanation of the general spirit of *laissez-faire*, which possesses most of our hospital staffs. The younger men are engaged in the grim struggle for maintenance, and the older men are enjoying the fruits of prosperity; so that the former cannot and the latter do not want to disturb the existing state of things.

(To be continued.)

ROCKEFELLER MEDICAL FELLOWSHIPS.

FELLOWSHIPS for the academic year 1930-1931 will shortly be awarded by the Medical Research Council, and applications should be lodged with the Council not later than June 1st, 1930. The Fellowships are provided from a fund with which the Council have been entrusted by the Rockefeller Foundation. They are awarded by the Council to graduates who have had some training in research work in the primary sciences of medicine or in clinical medicine or surgery, and are likely to profit by a period of work at a university or other chosen centre in the United States before taking up positions for higher teaching or research in the British Isles. In special circumstances they may be tenable at centres of research not in America. A Fellowship held in America will have the value of not less than £350 a year for a single Fellow, with extra allowance for one who is married. Travelling expenses and some other allowances will be paid in addition. Full particulars and forms of application are obtainable from the Secretary, Medical Research Council, 38, Old Queen-street, London, S.W. 1.

THE ESSEX COUNTY SANATORIUM.

ON Saturday last, April 26th, Mr. Greenwood, Minister of Health, opened the County Sanatorium of Essex at Black Notley, a mile or two south of Braintree, in the presence of a distinguished gathering which included the High Sheriff, the chairman of the county council, and the deputy lieutenants of the county. The original county scheme for the treatment of tuberculosis, framed in 1912, provided for beds in various existing hospitals and private sanatoria. Later on the council built its own sanatoria at Harold Court for men, at Black Notley for women, at Sible Hedingham for children, and at High Beech for surgical tuberculosis. Shortly before the war it was decided to establish a large sanatorium and a site at Sandon was purchased for the purpose but ultimately relinquished. Finally an additional plot of land, 25 acres in extent, was acquired adjoining the existing sanatorium at Black Notley, and Welwyn Builders, Limited, began their work in July, 1928. The lay-out is of the familiar extended façade with south-easterly aspect, the centre of the scheme being the King Edward VII. Memorial Hall, which provides a place of recreation, with seating accommodation for nearly 200 persons. On the right are the two children's pulmonary pavilions with 25 beds each for boys and girls, and on the left two adult pulmonary pavilions each with 25 beds. All the buildings are of light construction, the walls of hollow brick slabs built on reinforced concrete raft, roofed with double Roman tiles, and with wide verandas, which in the case of the pulmonary pavilions have glazed skylights. Two surgical pavilions for 31 patients each occupy the northern portion of the site and are connected by corridors with the operating block, which contains theatre, anaesthetic, sterilising and plaster rooms with sections for X ray and light treatment. There is also an isolation pavilion with six single-bed wards. The school block consists of two large classrooms, the south walls formed by large folding doors admitting a maximum of light and air. The water-supply is from a deep well on the site, from which water is pumped to a tower. There is a dual system of drainage, surface water being discharged into adjacent streams, and the excreta being carried to two filter beds with revolving sprinklers, the effluent being irrigated over the land. Four tennis courts, two grass and two hard, have been laid down. There is a large garden and an area planted with fruit trees. The work was carried out from the designs of the county architect, Mr. John Stuart, F.R.I.B.A., at a total cost, including the site, buildings, services, and equipment, of £100,800.

Goulstonian Lectures

ENTITLED

THE SIGNIFICANCE TO CLINICAL MEDICINE
OF STUDIES INCALCIUM AND PHOSPHORUS
METABOLISM.*The Third Goulstonian Lecture in 1930, delivered before
the Royal College of Physicians of London
on March 18th.*

By DONALD HUNTER, M.D. LOND.,

FELLOW OF THE COLLEGE; ASSISTANT PHYSICIAN TO THE LONDON
HOSPITAL.

MR. PRESIDENT, FELLOWS, AND GENTLEMEN,—In the first two lectures I referred to those factors which brought about an increased output of calcium and phosphorus from the bones. I shall now speak of certain conditions associated with defective absorption and utilisation of calcium and phosphorus which give rise to diseases of bone. I shall also discuss the storage of lead in the bones in chronic lead poisoning, and I shall conclude by stating briefly the contributions to therapeutics of the researches I have quoted.

IRRADIATED ERGOSTEROL.

Studies of calcium absorption and utilisation are necessarily more difficult than those of endogenous calcium metabolism. It is not surprising, therefore, that the voluminous literature on the subject of irradiated ergosterol throws little light upon its mode of action. Various workers^{1,2} have reported hypercalcaemia arising from its use. But the level of the serum calcium indicates only the height of the "calcium stream" and gives no indication of its direction of flow. This can be determined only by studies of the total calcium metabolism.

The effect of irradiated ergosterol on the storage of calcium in animals has been studied by Bauer and Marble.³ They placed 12 cats on a low calcium diet for some months, previous experiments having shown that such treatment causes a marked diminution of bone trabeculae. At the end of this period, the left forelegs of all the cats were amputated at the shoulder-joint. All 12 cats were then placed on a high calcium diet, 6 of the 12 being given irradiated ergosterol in addition. After some time the cats were killed, and in each case the right humerus was prepared for comparison with the left. The cats receiving irradiated ergosterol showed a much greater increase in the number of trabeculae in the right humerus than did the controls.

It therefore seems likely that irradiated ergosterol increases the amount of calcium which is absorbed from the gastro-intestinal tract, and that if this increased absorption occurs at a time when the body needs calcium, an increased deposition of calcium occurs in the bones. Complete metabolism studies on human subjects⁴ show that there is an increase in calcium absorption when irradiated ergosterol is administered. These findings corroborate those obtained with cats and explain why the use of irradiated ergosterol in the treatment of rickets and osteomalacia has met with such uniformly beneficial results.

Effects of Over-dosage by Irradiated Ergosterol.

Considerable interest has recently centred on the effects produced by the administration of excessive doses of irradiated ergosterol. Pfannenstiel⁵ found that such doses resulted in the death of young rabbits. Kreitmair and Moll⁶ extended this work and found that mice, rats, cats, rabbits, dogs, and guinea-pigs

died in periods ranging from 15 to 40 days with doses varying from 1 to 40 mg. daily. In all cases the animals lost weight profoundly, and post-mortem examination showed deposits of calcium salts in the arteries, lungs, kidneys, stomach, and intercostal muscles. Kreitmair and Hinzelmann⁷ have since confirmed this, and they have added the important observation that, when the experiments are of long duration, there is a decalcification of the bones which especially affects the ribs but also involves the extremities, spine, and calvaria. This mobilisation of calcium from the bones in "hypervitaminosis D" has been confirmed,^{8,9} and György¹⁰ has recorded experiments which seem to show that the spongiosa of bone is called upon first. In these experiments growing rats on a diet not very rich in calcium were treated with large doses of irradiated ergosterol. Hypercalcaemia occurred, and they lost appetite, weight, and hair. Post-mortem examination revealed macroscopic areas of calcification in the aorta and stones in the bladder. Controlled radiograms of the bones showed localised osteoporosis of the subepiphyseal spongiosa.

The Method of Irradiation of Ergosterol.

The work of Dixon and Hoyle¹¹ has shown that the pathological changes produced in such experiments on animals depend largely upon the manner in which the ergosterol is irradiated. In the case of material irradiated in oily solution—analogueous to the natural irradiation of the ergosterol of the skin by sunlight—no abnormal effects upon the weight curve and no post-mortem lesions were found in rats after the daily administration of doses up to 2 mg. for 45 days. Much larger doses administered daily for a corresponding period led to interference with growth and the formation of calcium phosphate calculi in the urinary tract. Calcium deposits in the kidneys, arteries, and other tissues were not present in these animals. The possible significance of these observations is not without interest in the aetiology of tropical urolithiasis.

The pathological effects produced in animals by administering similar doses of ergosterol irradiated in alcoholic solution are very much more severe than those described for material irradiated in oil. They consist essentially of intense marasmus and widespread calcification of the arterial system, myocardium, and kidney. Urinary calculi occur only rarely. Hoyle¹² has shown that the diet given in such experiments is a determining factor in the production of this pathological picture. All the lesions occur constantly in rats when a synthetic diet is being taken together with a daily dose of about 80,000 antirachitic units of irradiated ergosterol, and death is usual within two or three weeks. If a natural diet of bread and milk is given, together with these excessive amounts of ergosterol irradiated in alcohol, the animals remain well, except for some retardation of growth. After 30 or 40 days, post-mortem examination in such animals shows urinary calculi in some cases but no calcium deposits in any of the organs. These latter effects are identical with those produced by giving similar doses of ergosterol irradiated in oil, together with a synthetic diet. In other words, the effect of a natural diet is to deprive ergosterol irradiated in alcoholic solution of certain toxic properties. This is strong evidence against the view that vitamin D and the toxic factor responsible for the marasmus and calcification of tissues are identical, and it shows that "hypervitaminosis," as distinct from the toxic action, is not an entirely new type of toxæmia but only the exaggeration of a physiological action.

In recent work, Hoyle¹³ has extended these observations and has found that neither milk nor bread alone, when given with a synthetic diet, has any protective action. Further, a synthetic diet modified to resemble bread and milk as regards its carbohydrate, fat and ash content does not prevent the toxic action of ergosterol irradiated in alcoholic

solution. If the amount of the latter in a diet be increased still more, to such doses as 200,000 units daily, then bread and milk loses its protective effect. These results suggest that some previously unrecognised factor in diet is concerned in the protective action.

RICKETS AND OSTEOMALACIA.

Morbid anatomists are agreed that in rickets and osteomalacia the essential abnormality is the same—namely, a deficient calcification of osteoid tissue. This deficiency is generalised throughout the skeleton. In rickets, since endochondral ossification has not ceased, the zone of provisional calcification is affected too, and endochondral ossification is irregular.

The nature of the calcium deficiency has given rise to much controversy. Virchow¹⁰² held the view that calcium salts had been removed from calcified bone leaving osteoid tissue. This was the doctrine of "halisteresis," which means literally "salt deprivation." Pommer¹⁰³ and Schmorl¹⁰⁴ while expressing the view that osteomalacia and rickets are essentially the same disease, held in addition that halisteresis is not responsible for the broad osteoid zones. They considered that, in both diseases, the calcifying mechanism which should convert osteoid tissue into true bone was deficient. Not only does any bone added by advancing endochondral ossification remain osteoid, but so also does all new bone added to trabeculae which were fully calcified at the onset of the disease. The normal physiological resorption accompanies this apposition, and consequently portions previously hard become ever softer and more liable to bend.

Now, although there are many problems still unsolved concerning the aetiology of these two diseases, it is clear that the calcifying substance which is missing is vitamin D. In its absence the utilisation of calcium and phosphorus is impaired. Studies of the blood chemistry in children with rickets show that the essential abnormality is a low inorganic phosphorus content. The serum calcium is usually normal, but in a small proportion of cases it is reduced. In such cases tetany may occur. In osteomalacia a low serum calcium is the rule and tetany is very common.

In both diseases the abnormalities in the blood are promptly restored to normal by the use of cod-liver oil, ultra-violet light, or irradiated ergosterol. At the same time ossification begins to proceed normally. Biochemistry has therefore amply justified the view held by Pommer and Schmorl as to the pathogenesis of these diseases and as to their essential identity.

Clinical Features of Osteomalacia.

Osteomalacia is a deficiency disease endemic over wide areas in Northern India,¹⁰⁵ Japan, and Northern China,¹⁰⁶ and occurring sporadically in the Rhine Valley, Danube Valley, Vienna, and certain parts of Italy, Switzerland, Flanders, and the Balkans. It is a rare disease in the British Isles and U.S.A. It pre-eminently affects women, and is likely to recur earlier and with greater severity in each successive pregnancy. Many cases clear up after lactation is complete, or even before this time. However, it is a mistake to suppose that pregnancy is essential in its aetiology; it is sometimes seen at puberty, and is quite well known to occur, though it is rare, in boys and men. Maxwell¹⁰⁶ states that it is known to the Chinese as "Yao t'ui t'eng"—"back and thigh pain." The pain is aching in character and is worse in the winter months. The pelvis, thorax, or long bones show deformity in a haphazard way; one woman suffers in the pelvis, another in the ribs, and a third in both. Besides the characteristic and well-known changes in the pelvis, marked deformities occur in the chest and spine. Severe kypho-scoliosis may reduce the height by several inches and cause the head and neck to sink downwards and forwards on to the chest. Deformities of the sternum and ribs may give rise to marked prominences and depressions in the chest wall. Coxa

vara and irregular curves in the long bones are less common. The bones are soft and flexible rather than fragile, so that bending is much more common than spontaneous fracture, though both are well recognised. The patient develops a characteristic waddling gait, and muscular weakness may add to her incapacity. Tetany is very common, and the attacks may last for hours. In many cases the pelvic deformities interfere with marital relations or with pregnancy, Caesarean section frequently being necessary.

Pathogenesis of Osteomalacia.

It is only in the past seven years that real progress has been made towards solving the problem of the aetiology of osteomalacia. For almost half a century the hypothesis was held that the disease was due to a pathological increase in the activity of the ovaries leading to hyperaemia of the bones and a consequent solution of their lime salts. This was not based on accurate experiment, neither was there any evidence worth the name that the ovaries were histologically abnormal. The hypothesis arose in 1879 when Fochier¹⁰³ performed Caesarean hysterectomy in several cases of osteomalacia and found that a good effect was produced on the progress of the disease. Fehling¹⁰⁹ then set the fashion by performing ovariectomy for osteomalacia quite apart from pregnancy, and within a few years this treatment was performed all over the world. Now, while there can be no doubt that pregnancy leads to the development of osteomalacia, there is very little evidence that the ovaries exert any effect on the disease apart from their rôle in pregnancy. It is true that Mirvish and Bosman¹¹⁰ have shown that the injection of ovarian extracts into normal human subjects causes a reduction in serum calcium. On the other hand, the experiments of Korenchevsky¹¹¹ failed to show after castration any chemical or histological changes in the skeletons of growing rats fed on a normal diet. Castration presumably acts by stopping the possibility of further pregnancy and lactation with their consequent drain on skeletal calcium, and this can be as easily done by ligature of the Fallopian tubes.

An amazing fallacy regarding the aetiology of osteomalacia originated in the work of Bossi,¹¹² who arrived at a method for treating the disease with adrenalin by the following argument: "Since suprarenal substance is known through its pressor action to modify deeply the circulation of both sexual organs and bone marrow, since removal of the suprarenal has been shown in animals to cause deep and lasting changes in the ovary, I thought of treating this case with suprarenal substance (adrenalin)." After claiming, on quite inadequate evidence, that the patient was cured by the injections, he proceeded to an experiment upon a sheep in the middle of pregnancy. He removed one suprarenal and the animal remained well until the seventh day, when it had difficulty in walking. On the eighth day it could neither stand nor walk, and it showed "curvatures of the joints in the whole body, the hips markedly rotated inwards, and painful on pressure." Such is the evidence on which the suprarenal origin of osteomalacia is based. One asks oneself whether its exponents of to-day have troubled to read the article from which it sprang!

Studies in the mineral metabolism of osteomalacia date back many years, and began with analyses of the bones. McCrudden¹¹³ in a case of adolescent osteomalacia found 15.4 per cent. CaO in dried bone as compared to 28.8 per cent. in normal bone. In 1910 the same observer demonstrated a negative calcium balance in eight cases of osteomalacia.

The blood chemistry had not been studied accurately until Miles and Feng¹¹⁴ investigated ten patients in May, 1923. These cases varied in duration from 8 months to 20 years; in 7 there was tetany, and in all a considerable diminution in the serum calcium (5.0 to 7.4 mg. per 100 c.cm.). The plasma phosphorus varied from 1.8 to 3.8 mg. per 100 c.cm. The same workers carried out calcium

balance experiments on four adult females taking a low calcium diet consisting of millet gruel, wheat bread rolls, celery-cabbage, garlic, and dry steamed millet. A negative calcium balance was found in three patients, positive in one. Keeping the diet identical and adding cod-liver oil, alone or in combination with either calcium lactate or calcium phosphate, they were able to bring about marked retention. In one patient receiving olive oil with calcium lactate, the calcium balance remained negative. Osteomalacia therefore chemically resembles low calcium rickets. In the present state of our knowledge the occurrence of hyperplasia of the parathyroids in osteomalacia⁴⁴ is without explanation. Since all the parathyroids are usually affected, the hypothesis that the change is compensatory seems attractive.

Economic Factors Responsible for Osteomalacia.

With the story of rickets before us we can trace the economic factors operating in the causation of osteomalacia. They are factors difficult for a Western civilisation to appreciate, deep-rooted as they are in the social and religious customs of the East. The diet of the Chinese people is meagre, consisting, as in the experimental diet used by Miles and Feng, entirely of cereals and a limited amount of vegetables with no milk, meat, or eggs. It is deficient in vitamin D and in calcium salts, and contains an excess of acid-forming over base-forming mineral elements. The environment tends to keep the woman patient isolated from the sun, for foot binding retards movement, and the severe winters of the high plateau lands of North China lead to confinement indoors. When the pains of osteomalacia begin she retires to her warm brick bed thereby completely shutting herself off from the sun. In India the areas affected are in the North, in the high valleys where sunlight is scanty in winter owing to the surrounding mountains. As in China there is a marked seasonal incidence, the disease being worse in winter and early spring. The women affected are those observing strict purdah.¹¹² They are systematically screened from the sun from the age of ten. They eat no raw vegetable or fruit, largely from fear of cholera. The pregnant woman is kept short of food with the idea of keeping the foetus small for an easy labour. The calcium drain of lactation is very severe, for it commonly goes on as long as four years. Under such social systems it is not surprising that other deficiency diseases may exist together with osteomalacia. Thus Wampler¹¹³ reports oedema in one-third of 46 cases, and xerophthalmia in one.

In the treatment of osteomalacia, as in the case of rickets, cod-liver oil, sunlight, and irradiated ergosterol, each has its place. Vaughan¹¹⁴ reports that "out-patients given cod-liver oil and ordered to go out on the lake in open boats improved rapidly." Starlinger¹¹⁷ and Hottinger¹¹⁸ report cures with irradiated ergosterol, and it is an interesting fact that each of their cases had been previously treated unsuccessfully by ovariectomy. Maxwell¹¹⁹ states that "given cod-liver oil, good food and sunlight, the majority of the patients will slowly recover. Cod-liver oil and calcium salts quickly remove tetany and the worst of the pain." He finds that some cases require an ounce and a half of cod-liver oil with one milligramme of irradiated ergosterol daily. But he adds, "we want flocks and herds, milk and meat, with security of life and property."

Antenatal Rickets.

In the days of Virchow, several diseases of bone discoverable in the new-born were classed together as "fetal rickets." These have since been identified as achondroplasia, osteogenesis imperfecta, and cretinism. Maxwell¹²⁰ claims to have found true rickets in antenatal life. He took radiograms of the bones of the new-born babies of osteomalacic mothers, and demonstrated the typical changes of rickets in the metaphyses. Microscopic preparations of the bones were obtained from one case. In these,

Turnbull¹²¹ found changes attributable to a mixture of rickets or osteomalacia, with Barlow's disease. It is of some importance, too, that babies of osteomalacic mothers do get post-natal rickets, and that in China rickets is especially severe where osteomalacia is more common.

Hunger Osteopathy.

Occasional cases of hunger osteopathy were known¹²² before 1914, but the mass experiment of war caused large numbers of cases to appear in Austria, Germany, and Poland between 1917 and 1919. Concurrently rickets,¹²³ late rickets, osteomalacia,¹²¹ and Paget's disease,¹²² increased in incidence and severity. The people of industrial towns were most affected. Thus in Frankfurt the food was principally potatoes, watery soups, and dried carrots. Fresh vegetables were rarely obtainable. Meat, fish, and bread were rationed. Fat, butter, cheese, eggs, milk, and rice were completely absent. Hence the diet was deficient not only in total calories, protein, and fat, but also in calcium, phosphorus, and vitamins.

Clinically, the condition resembled early and slowly progressing osteomalacia. In age and sex incidence it was most peculiar. The majority of patients were elderly, and of either sex. Adolescents between 14 and 20 years were also attacked, and in this age-period two to four times as many males were affected as females. Children from 6 to 14 years were absolutely spared, and people from 20 to 35 years were almost wholly immune. The poorest were most affected. They looked prematurely aged, with sunken orbits and a sallow colour. Pain in the tarsus and metatarsus gave rise to difficulty in walking. Later there was pain in the sacrum and ribs, with a characteristic waddling gait and difficulty in mounting steps. The pains were always associated with movement. Many patients complained of cramp in feet, legs, or forearms. Tetany was not infrequent, and some cases showed positive Erb, Trousseau,¹²⁴ and Chvostek signs.¹²⁵ There was tenderness of the bones, so that compression of the ribs and sacrum and abduction of the thigh caused pain. A few patients gave a definite history of decrease in height. Spontaneous fractures were sometimes seen,¹²⁴ and occasionally deformities of ribs, sternum, and spine.¹²⁶

Dalyell and Chick¹²⁷ found a marked remission in the disease in Vienna in the late summer of 1919. In December, 1919, they found fresh and remitting cases in two convents in which the nuns had suffered severely during the previous winter. Between January and May, 1920, they treated 600 out-patients with the disease. For obvious reasons no investigation of the blood chemistry could be made. Calcium was found to be a specific. After a few treatments of the trunk became less painful, the patient could stoop or turn readily, the pains improved within a week. During the treatment there was less pain on abduction of the thigh. The most obstinate pains were the sacral and tarsal, which sometimes persisted throughout the commencement of treatment. In some cases tetany this improved before the pains, and in others the remission of symptoms preceded the disappearance of signs. From what we now know of the remission of symptoms in the disease, it is probable that no therapeutic measure would have been included vitamin D. It was only obtained where the disease was in its current disease. There is no doubt as to whether the condition was a true rickets, and this, of course, cannot be determined by histologist.

Schmorl¹²⁸ and Forster¹²⁹ regard the condition as an extreme degree of osteomalacia upon the rarefaction of the bone. "The condition is a true rickets, and is not a new disease." 3

McCrudden and Fales¹²² related osteoporosis and fractures to the negative calcium balance which they found in the disease. Lehnorff and Mautner¹²⁴ pointed out that a child with coeliac disease is liable to spontaneous fractures. I can find no record of histological examination of such bones. Coeliac rickets can be completely cured, even when the patient is on a fat-free diet, by ultra-violet light or irradiated ergosterol.¹²² It is, therefore, fair to say, even in the absence of histological records, that the combined evidence strongly favours a rachitic origin of the bony changes sometimes found in coeliac disease.

Idiopathic Steatorrhœas of Adults.

Since the description by Herter¹²⁵ of intestinal infantilism, later authors have paid attention only to cases of steatorrhœa in children, and have forgotten that Gee also observed the condition in patients returning from India and in adults who had never been abroad. The occurrence of tetany is not uncommon in tropical sprue. It is associated with a low serum calcium, and is no doubt related to deficient calcium absorption. However, it has been found¹²⁶ that severe and cachectic cases of sprue often have a normal serum calcium. The cause of sprue is unknown, and whatever calcium defect may be found is of secondary importance only.

Cases in adults of fatty diarrhœa with tetany, accompanied by extreme wasting, occurs sporadically in temperate regions. Of these it is equally true that the cause of the defective absorption of fat is unknown, and that the defect of calcium absorption is of secondary importance only. Thaysen¹²⁷ regards them as cases of non-tropical sprue, and includes them with sprue and with coeliac disease in the term "idiopathic steatorrhœas." Cases have been recorded of patients who had coeliac disease in childhood and recurring diarrhœa and tetany in adult life.

The fat in the stools is mostly split fat. There is pallor and sometimes severe anæmia.¹²⁸ In three cases I have found clubbing of the fingers. The abdomen is distended, and the colon may be dilated. Bone deformities are common and include genu valgum, genu varum, bowing of femora and tibiae, and spontaneous fractures. I have seen one case where osteotomy of each femur had been performed. Achlorhydria is common, and the blood-sugar tolerance curve may be low.¹²⁷ The plasma phosphorus is greatly reduced, and the serum calcium may be low. Metabolism studies¹²⁹ suggest that the chief factor concerned in the calcium defect is a failure to absorb vitamin D, and that the formation of calcium soaps is not an important factor in preventing calcium absorption. Treatment by fat restriction and irradiated ergosterol is sometimes effective.

CASE 8. Idiopathic steatorrhœa with tetany and dwarfism.—A single woman, aged 34 years (L.H., Reg. No. 40440, 1929). Clinical history: She was born at full-term and was the first of four children. She was breast-fed for 12 months, and afterwards took badly to milk. At five months she cut her first tooth, and at ten months she talked. At 13 months she began to walk, when it was noticed for the first time that her knees were wrong. She was a small child. The first and second dentitions were apparently normal. At five years she began to go to school, but could never run because of her knees. She had occasional short attacks of diarrhœa.

As a child she was usually top of her class in school. As she approached the age of 14 she became weak and stopped growing, and she had the early symptoms of what she afterwards learned was tetany. One morning in March in the year she was 14, she awoke with her hands stiff and with pains in wrists, ankles, and knees. Characteristic carpal spasm occurred. Her hair began to get thinner and became greyish. There was no change in the skin or nails. Nine months later menstruation began. Subsequent periods have been normal in amount and somewhat irregular, with intervals of five or six weeks.

Between the ages of 16 and 21 she was semi-invalid and had to be wheeled about in a bath chair. She then improved for a time, taking an interest in people and in books, but having to rest for a period every day. Attacks of tetany occurred about four or five times every winter and, later, sometimes in the summer. They had no relation to menstruation. Early attacks were confined to the hands and

feet; later ones affected also the shoulders, knees, neck, and face. Sometimes she was unable to speak for short intervals, breathing was difficult, and the eyelids twitched. Pain and spasms lasted up to two or three hours. Subsequently the muscles felt stiff and aching and remained so for three or four days.

At the age of 28 she began to have attacks of epigastric discomfort with abdominal distension, flatulence, and diarrhœa. There was complete loss of appetite (she had never been able to take milk or bacon fat). The diarrhœa often lasted several weeks. Sometimes attacks of tetany were associated with these disturbances, though there was no constant time relation between the two.

Family history: Father, mother, one sister, and two brothers alive and well. There is no history of dwarfism in the family.

Clinical examination: She is a tiny woman, thin, with the general contours of an adult, except that her head is

FIG. 14.

Idiopathic steatorrhœa with tetany and dwarfism.
(Case 8.)
Opacities in the lens, as seen with the slit-lamp.
(From drawing by Theodore Hamlin Ltd.)

Slit-lamp examination of lenses (Fig. 14). Collections of opacities in the lens similar to those seen in a case of post-operative tetany. There are central flaky opacities with some small crystalline opacities, some chromatic. Powdery opacities are seen in the nucleus of the lens. (Mr. C. B. Gouvenar.) Thyroid gland: present and normal in size. Hands: small and delicate in proportion to the rest of the body, resembling those of a child of 14. Trousseau sign positive. Chvostek sign never elicited. Knees: marked genu valgum, more pronounced on the right side, and so severe that she can stand only with her legs crossed, the right in front of the left. When the knees are placed together side by side, the feet are separated by eight inches. Spine: straight. Breasts: normally developed. Heart and lungs normal. Pulse regular, 82. Radial arteries normal. Blood pressure 146/90. Abdomen: rather protuberant, especially above the umbilicus.

Special examinations.—Urine normal. Urinary diastase index, 5. Renal efficiency tests: blood-urea 0.025 per cent. Phosphomorphalium excretion, 25 per cent., 12 per cent., 10 per cent., in successive hours. Urea concentration up to 3.30 per cent. Blood: red cells 4,600,000 per c.mm. Hemoglobin 62 per cent. Colour-index 0.77. White cells 6320 per c.mm. Polymorphonuclear neutrophils, 26.5 per cent.; eosinophils, 0.5 per cent.; small lymphocytes, 26.5 per cent.; large lymphocytes, 3.5 per cent.; large hyaline cells, 11.5 per cent. Serum calcium: 8.2 mg. per 100 c.cm. Plasma inorganic phosphorus: 2.4 mg. per 100 c.cm. Fractional test-meal: achlorhydria. Faeces: pale and porridge; three separate determinations of their fat content gave the following results:—

	Per cent.	Per cent.	Per cent.
Total fat	60	61	65
Unabsorbed fat	57	26	38

Radiographs of bones: There was a uniform diminution of density of X ray shadows of bones (Fig. 15) contrasted with those of a control subject of the same age, sex and build exposed simultaneously on the same negative. The epiphyses were united. The metaphyses of many of the long bones showed faint transverse "lines of cessation of growth" up to five in number.

The serum calcium curve.—The variations in serum calcium throughout the 13 months she was under observation are shown in Fig. 16. In March and April, 1928, it lay between 6 and 8 mg. per 100 c.cm. Then, during the three weeks when irradiated ergosterol was being given, with a daily

FIG. 15.

Case 8.—Controlled radiogram showing diminished density of X-ray shadows of bones in idiopathic steatorrhea. The negative has been cut down and the two portions placed together for close comparison.

intake of about 0.5 g. calcium, it rose steadily to 10.8 mg. After the irradiated ergosterol was discontinued it declined gradually, and in mid-June fell as low as 7.2 mg. In July and early August, under the influence of a high calcium diet and large doses of calcium lactate, it climbed steadily from 8.7 mg. to a maximum of 12.1 mg., and throughout August, when irradiated ergosterol was superadded, it remained between 11 and 12 mg. In September when the calcium intake was reduced to less than 1 g. a day, and a severe attack of intestinal discomfort with diarrhoea was in progress, it fell again, fairly rapidly, to 8.6 mg. During the winter a very slow and somewhat irregular decline continued, till on March 25th, 1929, the very low level of 5.0 mg. was reached. For most of this time up to Feb. 21st the calcium intake was below 0.6 g. daily, and the fat content of the diet was minimal. During March, when the calcium intake had been raised to 1.8 g. daily and the diet was also rich in fat, the decline continued. In April the intake was about 1 g. a day, and ultra-violet light treatment was begun. The result was a prompt rise in serum calcium level from 5.7 to 8.5 mg. in three weeks.

The observations thus show clearly that a definite rise in the serum calcium level could be produced by any one of three agencies, namely: (1) irradiated ergosterol (with low calcium intake); (2) high calcium diet with superadded large doses of calcium lactate; (3) ultra-violet irradiation.

The tetany.—Trousseau sign was present when she was admitted, and remained present throughout the rise of the serum calcium curve to 10.8 mg. in response to irradiated ergosterol. In the second, more marked, and better sustained rise, pro-

duced by high calcium intake and irradiated ergosterol, the sign disappeared when the curve reached 10 mg. and did not appear till it declined sharply 2½ months later to 8.6 mg. Even then it was not elicited in October when the serum calcium was 8.5 mg., but it reappeared in November and remained continuously present, except for two occasions in January, until the following April. Then following five days' exposure to ultra-violet light it promptly disappeared, while the serum calcium still remained at 6.8 and 6 mg., and was not again elicited before the patient's final discharge.

These observations show that there is a general relationship between the liability to tetany as tested by the Trousseau sign and the serum calcium level, in that the sign is present

TABLE III.—Chemistry of the Blood in a Case of Renal Rickets.

when the calcium is low and tends to disappear when it rises, but the relation is not a fixed or constant one. The disappearance of the sign after irradiation, before the serum calcium had risen above 6 mg., is very striking, and it may be significant that the period of absence of the sign during the time of high calcium intake and high serum calcium level (July and August) occurred at the height of the summer, when the patient was receiving a certain amount of sunshine.

Renal Rickets.

The clinical characteristics of renal infantilism or dwarfism are now well known. The stunting of growth and delayed union of epiphyses often occurs without clinical or radiological evidence of rickets. It is equally certain that rickets occasionally complicates renal dwarfism, and, in one such case, Prof. H. M. Turnbull has demonstrated all the histological

FIG. 16.

Case 8.—Chemistry of the blood in idiopathic steatorrhea with tetany and dwarfism.

The interval marks on the abscissa represent weeks. Where the calcium intake exceeds 2 g., calcium lactate had been added to the diet. The dosage of irradiated ergosterol was measured in antirachitic rat units. Ultra-violet light was given by the mercury-vapour quartz lamp. The presence of Trousseau sign has been charted as latent tetany.

characteristics of true rickets. And yet this condition is not due to lack of vitamin D, but to a disturbance of endogenous calcium and phosphorus metabolism for which the chronic nephritis is evidently responsible. It is generally supposed that phosphate retention, due to the renal defect, is primarily responsible for the changes in the bones. Table III, from a case of renal rickets in a boy of 17, shows how the plasma inorganic phosphorus rises with the rise in blood-urea. The serum calcium tends to fall as the plasma phosphorus rises, hence the high incidence of tetany in this disease.

Diagnostic Value of Serum Calcium and Plasma Phosphorus.

We are now in a position to consider the value of the serum calcium and plasma phosphorus used as an aid to diagnosis. In Table IV. the first three columns

TABLE IV.—Value, as an Aid to Diagnosis, of Serum Calcium and Plasma Phosphorus.

depict those conditions where absorption and utilisation are at fault. The plasma phosphorus is low in all three; the serum calcium is low, except in rickets where it is usually normal. In the last four columns are recorded repeated observations on the blood chemistry of individual cases, in all of which the endogenous calcium metabolism is at fault. Here an inverse ratio holds between calcium and phosphorus readings. In hyper-parathyroidism parathyroid hyper-function keeps the calcium high and the phosphorus low. In post-operative tetany and spontaneous hypo-parathyroidism, owing to parathyroid hypo-function, the reverse holds good. The result is that the serum calcium may be as low as

TABLE V.—Chemistry of the Blood in Osteitis Deformans.

Sex.	Age.	Serum Ca.	Plasma P.	Plasma phosphatase.

F.	60	9.5	3.2	1.2
M.	65	8.2	3.3	1.6

4.0 mg. per 100 c.cm., and the plasma inorganic phosphorus as high as 10.0 mg. per 100 c.cm. In renal rickets the plasma inorganic phosphorus is high, and the serum calcium low.

Osteitis Deformans.

In Paget's osteitis deformans the serum calcium and plasma phosphorus are approximately normal. Such

studies as have been made of the calcium balance have given conflicting results, but no departure from the normal of any magnitude has been demonstrated. The discovery by Kay²¹ that the plasma phosphatase is constantly high in this disease is of great interest (Table V.), though its exact significance has still to be discovered. It is useful in diagnosis though it is not pathognomonic, since high figures are also found in generalised osteitis fibrosa, secondary carcinomatosis of bones, and in some cases of exophthalmic goitre.

Osteogenesis Imperfecta.

In osteogenesis imperfecta (Table VI.) no abnormality in the serum calcium, plasma phosphorus, or calcium output has been satisfactorily demonstrated.¹⁴⁰ The plasma phosphatase is, in some cases, slightly raised. The cause of the defective osteoblastic apposition of bone is quite unknown. There are two cases recorded which showed enlargement of the parathyroids. The seven-months foetus described by Bauer¹⁴¹ had four enlarged parathyroids, the largest the size of the adult gland (3 mm. diameter). Histologically these showed hyperplasia. He relates

that Dietrich¹⁴² described another case. In the present state of our knowledge such observations are without explanation.

STORAGE AND EXCRETION OF LEAD.

Studies of lead poisoning have revealed a close analogy between the storage and excretion of lead and of calcium. Since lead is a cumulative poison there must be some place in the body where it can be retained in fairly large quantities. The work of Gussierow¹⁴³ in 1861, followed by that of Heubel,¹⁴⁴ showed that this storehouse was the skeleton. Minot and Aub¹⁴⁵ demonstrated quantitatively in animals and man a selective localisation of lead in the bones which becomes practically complete after absorption has ceased. Fairhall¹⁴⁶ studied such bones, and the results of his experiments suggest that the lead is present as the very insoluble tertiary phosphate. Various experiments showed that this is deposited in the calcareous portion of the bone and not in the marrow.

During different stages of intoxication by lead its distribution within the body varies somewhat. During slow absorption it migrates to the storehouse in the skeleton where about 95 per cent. is held without harm during the chronic stages of plumbism. However, if large quantities of lead are being absorbed or are being liberated from the bones, lead is distributed throughout the tissues and the percentage in the bones is reduced. Under these conditions symptoms of acute poisoning may occur. Working with human autopsy material, Minot and Aub have shown that the total amount of lead stored in the skeleton in lead workers varies from 0.2 to 0.8 g.

Lead stored in the bones may be gradually excreted in minute amounts over long periods. It has been found in the stools of persons who have been removed from exposure for more than two years, and Sir Thomas Oliver reports finding it in the urine of a woman 11 years after exposure. Thus, as suggested by Straub¹⁴⁷ in 1911, and by Erlennmeyer,¹⁴⁸ there may be an intermittent stream of lead entering the circulation to be excreted gradually.

Effect of Ammonium Chloride on Elimination of Lead.

Aub and Minot studied the conditions favouring and hindering liberation of lead from the bones in cats experimentally poisoned with lead. Early in their investigations they found that during starvation acute symptoms may develop, and at necropsy lead is found distributed more generally through the body than is typical of the chronic condition. This suggested that during starvation there is some abnormality in metabolism which sets free lead from the bones. Acidosis seemed the most probable explanation for the change, and an investigation based on this hypothesis was undertaken.

Lead workers were placed on a low calcium diet and were given either hydrochloric acid, phosphoric acid, or ammonium chloride in large doses. The excretion of lead in the faeces was markedly increased. The probable reason for the increased liberation of lead during acidosis is to be found in the experiments of Fairhall.¹⁴⁶ He studied the effect of variations in the hydrogen-ion concentration upon absorption of lead by bone. The tertiary phosphate of lead has an extremely low solubility at the normal pH of the body. However, under slightly more acid conditions, it is readily converted into the secondary phosphate of lead (PbHPO_4) which is a hundred times more soluble. Hence the ingestion of acid probably serves to liberate lead from the skeletal stores by converting it into a more soluble salt.

Effect of Parathyroid Extract in Lead Poisoning.

When active parathyroid extracts became available, the opportunity occurred for the direct confirmation of the hypothesis that the metabolism of lead is analogous to that of calcium. We²² kept patients with chronic lead poisoning on a low calcium diet, and then gave them parathormone, with a view to determining the total output of calcium and of lead. For, under these circumstances, any large and prolonged rise in the blood calcium and in the calcium excretion would occur at the expense of the skeleton, and it was our purpose to discover whether or not the lead deposits would be mobilised with the calcium.

Parathormone definitely increased the excretion of lead when first given (Fig. 17). The amounts excreted were far greater than those obtained when potassium iodide, ammonium chloride, or phosphoric acid were given. When parathormone was given a second time, little or no increase in lead excretion was observed, though the extract was known to be potent because it produced its characteristic effects on calcium metabolism. Evidently parathormone rapidly and effectively mobilises from the bones a certain amount of stored lead which is readily available. The remaining lead is mobilised much more slowly in the normal routine of metabolism.

In our six patients the rapid mobilisation and elimination of large amounts of lead produced no ill-effect. However, we are not unaware that the procedures we used were very drastic and, used without due care, might produce the acute toxic episodes of plumbism. The action of parathormone in lead poisoning confirms the theory that there is a striking parallelism between the storage and excretion of calcium and of lead.

CASE 9. Chronic industrial lead poisoning.—A man of 55 years (M.G.H., Reg. No. 273240, 1925) had been employed for seven years in the mixing-room of a rubber works where a powder containing oxides of lead was used for vulcanising. The occupation was very dusty. For two months he had had attacks of generalised abdominal pain with severe constipation. The pain had persisted every day, and was often sufficiently severe to double him up. He had had a similar attack three years before. Exposure to lead last occurred two months before admission.

On examination he had a sallow appearance and a marked blue line on the gums. The abdomen was flaccid and showed no tenderness. No abnormal physical signs were found in the nervous system. The red cell count was 3,120,000 per c.mm., with marked stippling of the cells. Hemoglobin 50 per cent. White cell count 8200 per c.mm.

Polymorphonuclears 60 per cent. Lymphocytes 30 per cent.

After treatment of the constipation and five days on a high calcium intake all pain ceased. The effects of treatment by parathormone are to be seen in Fig. 17. The general condition continued to improve. After three months the blue line on the gums was scarcely more than a faint speckling. The red cell count was 4,100,000 per c.mm., and very few stippled cells could be found. The hemoglobin was 70 per cent.

Storage of Other Elements in Bone.

There is a tendency for the selective localisation in bone not only of lead but also apparently of arsenic,¹⁴⁹ mercury,¹⁵⁰ silver,¹⁵¹ and radium. Recently Flinn and Seidlin¹⁵² have used parathormone in an attempt to increase the elimination of radium from the bones in factory workers poisoned by radium and mesothorium compounds. Such poisoning is known to occur where girls employed in painting the dials of luminous watches are in the

FIG. 17.

Case 9.—Effects of parathyroid extract and diet upon the excretion of lead and of calcium in lead poisoning.

The interval marks on the abscissa represent five days.

In the upper portion of the chart is shown the lead excretion. The faint line is the excretion of lead in the urine expressed in output for three days. The heavy line is the total excretion of lead in the urine and faeces for three-day periods.

In the middle portion of the chart the upper blocks represent treatment by parathormone; the adjacent scale represents units per day. The lower blocks represent the calcium intake in three-day periods, and, where the figure exceeds 0.7 g., calcium lactate had been added to the diet. The areas which have no enclosing block-line represent periods of unweighed high calcium diets. The faint line is the excretion of calcium in the urine expressed in output for three days. The heavy line is the total excretion of calcium in urine and faeces for three-day periods. The distance between heavy line and blocks, therefore, represents the positive or negative calcium balance.

In the lower portion of the chart is shown the blood-plasma calcium.

habit of pointing their brushes with their lips. Necrosis of the jaw and aplastic anaemia may result from the poisoning, alpha radiation being enormously destructive of the bones in which it is stored and also of the adjacent haemopoietic marrow.

USE OF CALCIUM SALTS IN THERAPEUTICS.

A survey of the results of calcium administration in disease at once shows that, as a therapeutic agent, it has proved disappointing. The constant supply of calcium in the food and the large available store in the bones make it unlikely that the regulating mechanism ever lacks calcium for distribution throughout the body. It is when the function of some part of this mechanism breaks down that the tissues suffer from calcium deficiency. It therefore follows that the use of cod-liver oil, ultra-violet light, irradiated ergosterol, parathyroid or thyroid extract is often of greater value than the direct administration of calcium salts.

Need for a Diet Adequate in Calcium.

The use of well-balanced diets is not a necessary counterpart of an advanced civilisation. Thus it has been calculated¹¹⁴ that the diet of the Finns contains between 2 and 6 g. CaO daily, whereas the equivalent figure for the average diet in the U.S.A. is only 0.45 g. Sherman¹¹⁵ regards this figure with some alarm since he considers that one gramme a day is really required. He urges the use of "calcium carbonate or phosphate habitually added to human food by mixing it with table salt . . . or a more liberal use of milk, which is an important source of proteins of high nutritive efficiency and of the fat soluble vitamin as well."

If, then, a diet containing little calcium is to be regarded as a potential source of harm, how much more harmful must be the food consumed over large areas of China and India. There the diet may be deficient in calcium or phosphorus, may contain an excess of acid-forming over base-forming mineral elements, and above all is very likely to be deficient in vitamins or to be consumed by women kept in darkness.

A high calcium diet of adequate vitamin content is required by pregnant and lactating women to allow for the drain of calcium into the foetus and especially through the mother's milk.

Owing to the great loss of calcium from the skeleton in exophthalmic goitre, attention should be paid to the mineral content of the diet in this disease.

Tetany.

In post-operative tetany success in treatment will vary according to how much parathyroid tissue has been destroyed. Calcium lactate may be employed as a powder taken fasting in repeated doses up to a total of 10 to 30 g. daily. In our experience these large quantities have never caused discomfort of any sort. Too often a few grains are given, in which case we can hardly expect much effect, since we know¹¹⁶ that in normal individuals the maximal rise in serum calcium after a dose of 10 g. is only 14 per cent. More severe cases require parathyroid extract in addition to calcium salts, and even this may be ineffective when extirpation of the glands has been extensive. The onset of laryngeal spasm, bronchial spasm, or convulsions demands intravenous therapy: 20 c.cm. of a 5 per cent. solution of calcium chloride may be injected into a vein, and, if given very slowly, no ill-effects are produced. The use of thyroid extract and irradiated ergosterol in post-operative tetany has hardly passed the experimental stage.

Cameron¹¹⁷ recommends the intramuscular injection of 1 g. of calcium chloride in infants with laryngismus. In the tetany of rickets or osteomalacia the use of parathyroid extract is contraindicated except in emergency, since the increased serum calcium is brought about by the removal of calcium from the bones, which are already deficient in it. The administration of cod-liver oil or ultra-violet light may be all that is necessary for the proper treatment of the rickets or osteomalacia and for the relief of the tetany.

Lead Poisoning.

In the prevention of industrial lead poisoning a diet of high calcium content plays its part. In lead works in this country it has for many years been customary to supply the workmen, free of cost, with a glass of milk in the morning. This is empirical treatment of considerable merit, anticipating as it did by many years the discovery that a high calcium intake assists the storage of lead in a harmless form in the bones.

The toxic episodes of lead poisoning—namely, lead colic, lead palsy, and meningo-encephalopathy—may be regarded as urgent indications for calcium therapy. In this country the Home Office Regulations, by control of dusts and fumes, have abolished meningo-encephalopathy, but it would be idle to suppose that lead colic and lead palsy have disappeared from industry. It is difficult to estimate the death-rate in meningo-encephalopathy; it is probably quite high. Aub¹¹⁸ states that of six cases three recovered promptly when given large quantities of milk and calcium lactate, and three died without such treatment. During the development of lead palsy a high calcium diet should be used to favour storage of lead.

After the acute toxic episodes have passed, elimination of lead may be accelerated by the use of a low calcium diet together with ammonium chloride. This is administered cautiously in 1 g. doses given in a glass of water six or eight times a day. Provided there is no nausea or headache this treatment is continued for two or three weeks, the patient being kept on a diet containing a strict minimum of 100 mg. of calcium a day.

Should any toxic episode appear, ammonium chloride must be stopped and a high calcium diet used to favour the storage of lead.

It is necessary to emphasise the difference between the use of agents assisting the excretion of lead and those assisting its storage. The acidosis method of lead elimination is so potent that its use during colic or meningo-encephalopathy might prove fatal, from the further mobilisation of lead at a time when the reverse procedure is essential in treatment.

Colic.

The question of the relief of lead colic by calcium therapy involves more than simply the tendency to favour storage; there is evidently an anti-spasmodic action on involuntary muscle. The only experimental evidence bearing on this is that of Kennedy,¹¹⁹ who reported that by increasing the calcium content of the fluid bathing the uterine strip, the result in the uterine muscle was both a loss of tone and of peristalsis. The pain of lead colic is probably due to a contraction of the tonic ring in the intestine with marked peristalsis approaching this. A high calcium diet usually brings relief within 48 hours. In severe cases, by the slow intravenous injection of 15 c.cm. of a 5 per cent. solution of calcium chloride, it is possible to relieve the pain by the time the injection is over. The patient feels hot and flushed and may vomit. The effect on the pain is very striking and is far superior to that of any other means of therapy. Should it be necessary, the injection may be repeated in two hours.

By the same method Aub has brought about prompt relief from renal colic and gall-stone colic. Theoretically the relief of spasm should help in the passage of the stone, but this remains to be seen. An additional advantage of this method is that a differential diagnosis between the pain of renal colic and appendicitis can be made, the former being relieved promptly, the latter persisting.

Edema and Inflammatory Exudates.

French workers, notably Blum,¹²⁰ have pointed out the diuretic action of calcium chloride in oedema. This is not a specific effect of calcium; it apparently results from a change in the balance of ions in the body fluids. Blum maintains that by increasing the calcium ions the sodium ions are decreased, and, since the retention of fluids is closely associated with the retention of sodium, the oedema is decreased.

Fraser¹⁵⁸ offers an alternative explanation. He points out that since ammonium chloride acts in a similar manner it is probably the acid properties of these salts which are responsible for their diuretic action, though the calcium may have an effect in the same direction by its antagonistic action to sodium.

Blum has extended his observations to inflammatory exudates and has reported beneficial effects in pleural and peritoneal effusions and in conjunctivitis. Workers on similar lines claim beneficial results for the administration of calcium chloride in asthma, angioneurotic oedema, and urticaria.

Acute Necroses of the Liver.

The accidental discovery by Minot¹⁵⁹ that a low calcium diet rendered dogs more susceptible to carbon tetrachloride poisoning led her to investigate extensively the chemistry of the blood in acute necroses of the liver.

Carbon tetrachloride causes a severe intoxication in dogs on a meat diet, while the addition of calcium salts to such a diet produces a high degree of tolerance to the drug. The symptoms of poisoning are gastro-intestinal irritation and hyperexcitability, followed by depression. There is a retention of guanidine in the blood and a hypoglycæmia. The relief and protection given by calcium seem to depend upon its antagonistic effect to the retained guanidine. When calcium is administered to poisoned animals the nervous symptoms are relieved and the blood-sugar is restored to normal. However, if the blood-sugar is raised by the administration of glucose, the hyperexcitability persists until calcium is given in addition. Similar results were obtained in a study of chloroform poisoning in dogs.

The investigation was then carried to liver disease in the human subject and more especially to eclampsia. Some cases showed hypoglycæmia and guanidine retention, and, where this was the case, prompt symptomatic relief followed the intravenous injection of 10 c.c.m. of a 10 per cent. solution of calcium gluconate. For example, in a woman with eclampsia who was semi-conscious and blind, within 15 minutes of the injection the vision was much improved, within 40 minutes the sight was restored, and the blood-sugar raised towards normal. Though the number of cases studied was small it is clear that such a highly protective action of calcium salts against liver poisons is worthy of further investigation.

Milk Fever of Cows.

The essential clinical feature of "parturient paralysis" or "milk fever" of the cow is tetany. It may be confined to the hind limbs or it may be generalised. It is followed by deep coma and often by death. The cause of the condition is unknown but acute hypocalcæmia^{160 161} is the determining cause of the symptoms. In its treatment inflation of the mammary gland has been practised for many years. It is now known that mammary inflation produces a rapid and regular rise in the blood calcium, and that this rise is concurrent with, and bears a direct relation to, the disappearance of the symptoms of the disease. Intravenous and subcutaneous injections of calcium gluconate¹⁶² have been used successfully in treatment. It has been shown in the sheep¹⁶² that "lambing sickness" or "ewe distemper" is identical in its essential pathology with "milk fever" in the cow.

[The lecturer closed with acknowledgments for grants received at various times towards the expenses of his work from the Yarrow Research Fund, the National Lead Institute of North America, the Rockefeller Foundation, the Ella Sachs Plotz Foundation, and the British Medical Association. He also thanked Prof. Aub of Harvard, Prof. H. M. Turnbull for their expert collaboration, and various colleagues on the staff of the London Hospital for the use of their cases and help in the wards.]

CHRONIC STREPTOCOCCAL ILLNESSES.*

By C. BRUCE PERRY, M.D. BRIST.,

M.R.C.P. LOND.,

COLSTON RESEARCH FELLOW, UNIVERSITY CENTRE OF CARDIAC RESEARCH, GENERAL HOSPITAL, BRISTOL.

THE chronic illnesses commonly attributed to the streptococci are so varied and different, and the aetiological rôle of the streptococci in their production is or has been so hotly debated, that the best way of considering them as a whole is to review the evidence of a streptococcal origin of the main chronic streptococcal illnesses in turn in order to see what their relationship is, if any, and what are the factors which make any one disease different from the others. It may be urged that rheumatic carditis and ulcerative endocarditis are not chronic illnesses, but both of them may run a course of many months. Further, their consideration in conjunction with the others may help to throw some light on the obscure problems of streptococcal infection.

The first record of the association of streptococci with rheumatic carditis was that of Birch-Hirschfeld in 1888.¹ Thereafter, various observers reported streptococci, among others, as the causal organisms, until in 1900 Poynton and Paine² described the organism which they labelled *Diplococcus rheumaticus*. This was practically the start of the "streptococcal theory" of rheumatic carditis. Since that time different workers have found streptococci, but almost an equal number have recorded negative findings. When the streptococcus in question is identified more completely it is found to be non-hæmolytic and gives similar sugar reactions to those of the streptococci normally inhabiting the alimentary tract. Horder³ showed that the same organism is the commonest infective factor in subacute bacterial endocarditis, and suggested that the cases of "malignant rheumatism" from which Poynton and Paine isolated their organism were actually cases of subacute bacterial endocarditis—a very important criticism if it is correct. The streptococci described by different workers showed minor variations in cultural characteristics, and Swift and Kinsella⁴ pointed out that if streptococci have any causal relationship to rheumatic carditis no one type of the an-hæmolytic group is concerned. Neither has it been possible with any degree of constancy to demonstrate agglutinins or other antibodies in the patient's blood to the organisms recovered from him. Animal experimentation, too, is negative, as no undoubted rheumatic lesion has yet been produced in animals. Injection of "rheumatic" streptococci produces arthritis and endocarditis, exactly as do injections of alimentary streptococci, but in all these cases the endocarditis is of the ulcerative type, and no rheumatic myocardial lesions are produced. The one exception is the possible production of "rheumatic nodules" by Clawson⁵ by subcutaneous injection of an-hæmolytic streptococci.

A fresh impetus to the streptococcal hypothesis was given in 1927 by Small⁶ who described the "*Streptococcus cardio-arthritis*" which produced a soluble exotoxin from which an antiserum was prepared. This antiserum is said to give encouraging results therapeutically. Birkhaug⁷ then investigated the skin reactions produced by the exotoxin of a non-methæmoglobin-producing streptococcus obtained from cases of rheumatic fever. He found that a far higher percentage of patients who had suffered, or were suffering, from rheumatic fever gave a positive reaction than did normal healthy people. Irvine-Jones,⁸ Kaiser,⁹ Hart,¹⁰ and others described similar findings, but there is no conclusive evidence whether the positive skin reaction indicates a susceptibility

to infection, or a sensitised allergic state of the patient similar to the tuberculin reaction. The skin reaction showed no specificity to any one strain, and the investigators suggest that a rheumatic infection is an allergic response by patients previously sensitised to the common streptococci of the respiratory and alimentary tracts. Hitchcock and Swift¹¹ have shown in rabbits that different groups of the "indifferent" streptococci possess varying degrees of allergising capacity, and that the rabbits also show variations in their reactive capacity to any one organism from the allergic standpoint. Faber's¹² experiments are suggestive, showing that a previous infection of one joint by streptococci, when followed by a later intravenous inoculation, constantly produces arthritis in that joint. Intravenous injection with no previous sensitisation is without effect until repeated at least two or three times, which suggests an analogy to the primary development of the lesion of rheumatism in man.

The conclusions drawn by Coombs and Poynton¹³ in the British Medical Association Report sum up very well the present position. They say that while the case for the streptococcal theory is not proved, it has as yet no rival. The more recent skin reactions and the allergic theory have rather strengthened the case for the streptococcal origin of rheumatism, so that it seems quite fair to include this as a chronic streptococcal illness, for the chronic smouldering character of the infection has long been recognised clinically.

Endocarditis.

The nomenclature of endocardial lesions is at the moment very confused because various workers have attempted to describe different clinical groups under differentiating names. However, as the aetiology and morbid anatomy of these groups essentially differs only in the virulence of the infecting organism, the condition may for convenience be called ulcerative endocarditis, which serves to distinguish it from the endocarditis associated with rheumatic pancarditis. The pathology of the acute fulminating cases which follow a general septicæmia is obvious, and they usually run an acute course, so that they can hardly be included as a chronic illness although a large percentage of them may be due to a virulent hæmolytic streptococcus. A large proportion of the sub-acute or chronic group, cases which may frequently run a course of over 12 months, and may, therefore, with some justification be called "chronic," are due to a streptococcal infection. Schottmüller¹⁴ was the first to describe a streptococcus isolated from the blood of cases of endocarditis. This streptococcus was non-hæmolytic, and as it produced a green coloration when grown on blood-agar he called it *Streptococcus viridans*. Andrewes and Horder¹⁵ and Gordon¹⁶ showed that this organism belonged to the common types of streptococci found in the alimentary canal. Many workers have confirmed these findings, and statistics from various sources show that as many as 75 per cent. of cases of endocarditis may be shown to be due to an infection with the streptococcus.

The outstanding point in the aetiology of ulcerative endocarditis is the frequency with which this condition follows congenital cardiac defects and rheumatic carditis. The lesion is always localised and only spreads by direct implantation, and the myocardial lesions are embolic only—that is, the condition is purely an endocarditis. Recently, Grant¹⁷ has shown that congenital defects and also previously damaged valves are frequently the site of small fibrinous deposits. Apparently organisms which, by some temporary breakdown of the surface resistance, have entered the blood stream, settle on these fibrinous tags and form a nidus of infection, in which they are safe from the normal bactericidal action of the blood. Presumably, such temporary invasions of the blood stream by the normal flora of the alimentary tract are not infrequent and are usually dealt with successfully by the normal antibodies. The infection and the localisation

*Awarded the Buckton Browne prize for 1929 by the Harveian Society of London, by whose permission it is published. Working under a Colston Research Fellowship.

cannot be due to a loss of general resistance because of its localisation, and also because patients with such a lesion show a very high antibody content in their blood against the infecting organism, as has been shown by Kurtz and White¹⁷ and other workers. Yet these patients are powerless to deal with the local infection and die, either as the result of large emboli or from uræmia, the sequel of embolic nephritis, or from cachexia and general toxæmia, from the repeated bombardment of the whole body with minute emboli. The local lesion, even the presence of the organisms in the peripheral circulation, appears to play a very small part in the actual illness. Further, cases of ulcerative endocarditis due to organisms other than streptococci show no clinical and very slight, if any, pathological differences from the streptococcal infections.

It has been repeatedly shown that the injection of streptococci of the alimentary tract into animals will reproduce the clinical and pathological picture of endocarditis in animals. A similar condition occurs in pigs after swine erysipelas. This disease, which is due to *Bacillus rhusiopathia suis* and is essentially an acute specific fever associated with a septicæmia, is followed in a certain number of cases by an endocarditis. This runs a very slow and protracted course, and corresponds in all essentials with the endocarditis occurring in man as the result of infection with a streptococcus of low virulence. It is clear that the organism itself is not the important factor of the disease, but rather a peculiar condition resulting from the localisation of the infective process.

Focal Infection.

It has been said that the pathology of focal infection is largely the pathology of the streptococci.¹⁸ This being so, focal infection and its results obviously constitute one of the chronic streptococcal illnesses. The evidence for the existence of "focal infection" as a cause of chronic illnesses is rather vague and indefinite. The main "proof" seems to be that a condition improves after the removal of some septic focus, but this by no means proves that the condition was due to the focus of infection. It may improve after the removal of the "focal infection" for the simple reason that the patient's general condition is improved, without there being any closer relationship between the two infective processes. The case for focal infection is also weakened by the countless people who for years carry about septic tonsils or chronic apical dental infection and yet never develop any secondary condition. These cases show that if focal infection is a cause of chronic illnesses, even including vague general ill-health, the important and deciding factor in its occurrence is not the infection nor the infecting organism but the patient. The illness most confidently ascribed to focal infection is chronic arthritis, but so confused is this at the moment by the conflicting opinions as to nomenclature and types that even here its ætiological rôle does not seem too certain. However, if we accept the classification adopted by Douthwaite¹⁹ and divide chronic arthritis into atrophic or rheumatoid, hypertrophic or osteoarthritis, and chronic infective arthritis we find that in the last group a very large percentage of the patients do present septic foci, and that the efficient removal of these leads to the cure of the condition. But there is very little, if any, sound evidence that the other two groups are due to "focal infection."

Apart from these "general" illnesses, streptococci may produce chronic "local" illnesses. These are of the nature of surface infections, and include such lesions as chronic tonsillitis, chronic bronchitis, and nasal sinusitis. In all of these the infection is usually a mixed one in which, however, streptococci predominate, amongst other organisms of doubtful pathogenicity. In apical dental infections, too, the most constant bacteriological findings are streptococci. In many such "local" infections the patient experiences no trouble except the local condition.

In others he suffers from vague indefinite ill-health which improves after the eradication of the septic focus. This class includes cases like secondary anæmia or indefinite dyspepsias which clear up on removal of the dental sepsis. In yet another group the condition is associated with a definite disease entity, such as chronic infective arthritis. There appears to be no correlation between the degree of local damage or the type of infecting organism and the general systemic lesions. As has been pointed out, alleviation of the disease after the removal of the septic focus is not proof that the latter is the cause of the former, but it is certainly very suggestive. If this be accepted as a working hypothesis, it is clear that the one factor which is responsible both for the occurrence of systemic lesions and for the type they may take lies in the patient and is not a property of the infecting organism.

Recently, Wilkie²⁰ has produced evidence that a chronic cholecystitis is due to a blood-borne mural infection of the gall-bladder with streptococci. He claims to have shown also that the streptococci have a selective localisation, and pick out the gall-bladder, leaving other organs unaffected. It is interesting to note that repeated intravenous injections were necessary to produce cholecystitis with calculi in rabbits. This touches on the theory of elective localisation, so ardently championed by Rosenow. While admitting that certain organisms, such as *Bacillus typhosus* and the pneumococcus, do show a predilection for certain organs, one cannot help feeling that the evidence that the streptococci exhibit similar characteristics is as yet far from convincing. Trauma or previous sensitisation do definitely exert a localising effect, but that any one group of the streptococci possess the property of picking out one organ for the site of their activities requires more proof than is as yet forthcoming. Rosenow would go further than this, as he believes that organisms isolated from the tonsils of a patient suffering from appendicitis will produce appendicitis on animal injection. This work has received much criticism and very little confirmation, and up to the present time his case is very far from proved.

The Absence of Specificity.

When one reviews the wide range of chronic illnesses which are at the moment attributed to streptococci one is struck by the fact that there is no specificity in the type of streptococcus producing the lesion. The hæmolytic streptococci are rare as the causal organism of a chronic illness, so rare that in fact their occurrence may be doubted. The types which are found in these chronic illnesses are of the non-hæmolytic or *viridans* group. The difficulty of any accurate method of classification of the streptococci introduces an obvious difficulty into any discussion of their effects, but the conclusion which emerges from the large mass of work done on the subject points to the fact that this group of streptococci are not specific. Any of them may produce any of the lesions. The production of pathogenic effects depends apparently on the host, its previous environment and infections, and on the mode of entry of infecting organisms. In ulcerative endocarditis we are beginning to know some of the factors which turn a transient blood infection with an indifferent streptococcus (an event to which we are all probably subject at any time) into a lethal disease. We know that a very large percentage of the cases occur in patients who are the subjects of previous heart disease, either congenital or acquired. In the other diseases, the predisposing factors may be more subtle and elusive, of the nature of defects in the humoral defences rather than morphological defects, but they are there, and they are the important ætiological factor in the production of the disease. Further, Hitchcock and Swift²¹ have shown that indifferent streptococci possess peculiar properties as allergising agents, which are not shown by any other organism. The various organisms in this group show variations

in this property, but it is common to them all in a greater or lesser degree; moreover, the reactive capacity of the inoculated animals varies widely with the same specimen. Derrick and Swift^{21, 22} have shown further that the hyperergy or allergy produced is not strain-specific and depends more on the method of inoculation than on the streptococcus used, and that in animals states varying from a high degree of immunity to a high degree of hypersensitivity may be produced, and moreover the hypersensitivity may be local.

The conclusion to which one is forced, both from experimental and clinical observation, is that the important factor in chronic streptococcal illnesses depends not so much on the infecting streptococcus as upon its mode of entry into the host, upon the host itself, and its previous experiences with the indifferent streptococci. Such a theory holds out a hope that one day we may be able to deal effectively with the chronic streptococcal illnesses. It is obvious that it is useless to try to deal with such infections on the same lines as those which are effective in dealing with diseases like typhoid or plague. In these infections we are able to a large extent to eradicate the infecting organism, but the streptococci are unfortunately ubiquitous. The solution of the problem lies in a better understanding of bacterial allergy and immunity. When we have discovered the difference between complete immunity, which makes the patient safe, and the dangerous state of allergy or hypersensitivity, which is apparently a partial or perverted immunity, we shall have discovered the key to the practical treatment of the chronic streptococcal illnesses.

PRINCE ALFRED HOSPITAL, SYDNEY.—The in-patients admitted during the year ended on June 30th, 1929, numbered 9520, of whom 5016 contributed towards the cost of their maintenance. This number is a record for any general hospital in the Australian Commonwealth. In the year the out-patients rose from 49,386 to 66,657, an increase partly due to the opening of the radium clinic—616 patients presented themselves at this special department. The average residence of in-patients was 20.70 days. At 1902 the number of operations has much more than doubled since 1913. The congestion in the out-patient department is such "that the situation is daily becoming quite intolerable," and the hope is expressed that the new State Hospital Commission will speedily provide the means for erecting new admission and casualty departments. The financial situation is "very much in the nature of a continuous nightmare." The year closed with a deficiency exceeding £23,000, besides an overdraft, guaranteed by the Government, of almost £112,000. The State subsidy for the year was £66,400.

MICRO-ORGANISMS IN PSITTACOSIS.

By ALFRED C. COLES, M.D., D.Sc., F.R.S. EDIN.,
M.R.C.P. LOND.,

PHYSICIAN TO THE ROYAL NATIONAL SANATORIUM AND
CONSULTING PHYSICIAN TO THE ROYAL VICTORIA
HOSPITAL, Bournemouth.

HAVING regard to the interest shown in and the numbers of workers engaged on the small and probably short-lived outbreak of psittacosis in this country, I venture to record my findings in this preliminary note. Thanks to the kindness of my friend Dr. G. T. Western, of the Inoculation Department of the London Hospital, I have been able to examine a few films of blood from this disease. Dr. Western at first sent me two air-dried blood films from a woman suffering from psittacosis, dated Feb. 18th, 1930. These I fixed in alcohol and stained in Giemsa for 9 and 30 hours respectively, the stain in the latter case being renewed two or three times. With an entirely open mind I carefully examined these films, step by step, using a one-tenth inch oil immersion objective and compensating ocular 0—i.e., with a magnification of about 600 diameters, looking for the unknown, whether protozoa, bacteria, or virus bodies. After a very exhaustive, and even more exhausting, search of one of these films, extending over 28 hours, I found a few organisms which were definite enough to be suggestive. On examining the second film and looking more particularly for similar organisms, I found a very few quite definite specimens. Subsequently Dr. Western was good enough to send me the following:—

1. Air-dried films made from the blood, spleen, and liver of a hen successfully inoculated with human material on Feb. 26th.
2. Two air-dried films made from citrated blood from a case at Eastleigh, dated March 1st.
3. A small tube of citrated blood from a case at Guy's Hospital dated March 4th. The resident medical officer at Guy's Hospital later kindly sent me blood films from this case, a woman aged 19, on the twentieth day of disease, dated March 12th.
4. Films from heart blood and spleen of a mouse, M.12, inoculated on March 14th from a parrot which died of the disease on the 20th.
5. A small quantity of the filtrate from the spleen of a mouse, M.28, which died, four days after the inoculation, on March 26th. Subsequently Dr. Western informed me that this filtrate was virulent and produced the disease in a mouse.

In all these cases the method adopted was the same. The air-dried films were fixed in alcohol and stained in Giemsa. The citrated blood was centrifuged and films made from the deposit, whilst a small drop of the filtrate was spread on a perfectly clean slide, and when dry these were stained in exactly the same way.

The Organisms Found.

Very similar if not identical organisms were found in all these specimens—viz., minute diplococci and coccoid bodies, and in most cases a very few small bacilli or diplobacilli. The most characteristic were the diplococci bodies, which consisted of two minute well-defined dots, varying slightly in size and usually staining red with Giemsa. In a few films, especially in preparations made from citrated blood, they stained a pale blue. The average measurement of these paired cocci is about 0.6 to 0.7 μ in length, and about 0.3 to 0.4 μ in diameter. In one of the human blood films two or three ordinary cocci and diplococci were seen, and the contrast in the size and the deep-blue staining of these with the minute, generally red-staining diplococci bodies found in this disease was very striking. Isolated coccoid bodies were also seen, but of course they were not as conspicuous as the paired bodies.

The bacilli were very thin rods measuring on an average about 2 μ . very sharply defined, and

usually staining a red colour with Giemsa, but in a few films having a blue tint. On very careful examination of typical examples they are seen to have a division in the centre, so that they apparently consist of two minute bacilli. A few bacilli stained red were found to be somewhat longer, reaching 3 or even 4 μ in length, and some of these showed a beaded appearance. The diplococcoid forms were found in very small numbers in all the cases, but the bacilli were extremely scanty, only three to five being found in a film.

The coccoid and paired coccoid bodies were more numerous in the blood and especially the spleen of

Film from the spleen of an inoculated mouse showing free and intracellular groups of the coccoid α bodies of psittacosis.

the hen, whilst in the liver of the hen they were not much more numerous than in the blood. The filtrate from the infected mouse was examined in Giemsa-stained films, in preparations made with Indian ink, and with nigrosin as in Burri's method, and by dark-ground illumination. A very large number of minute coccoid bodies was shown by all these methods, but, as was anticipated, considerably fewer diplococci were present.

Distinctive Bodies in the Spleen of the Inoculated Mouse.

Films of the blood of the inoculated mouse showed relatively numerous coccoid and diplococcoid bodies, and two or three red-stained bacilli were also found. But the films made from the spleen of the same mouse showed the most important and suggestive structures. Here I found not only isolated and scattered coccoid and paired coccoid bodies but, on prolonged search, I came across several groups or clusters of these structures. These agglomerations, which were for the most part lying free, varied in size according to the compactness or otherwise of the granules, and generally measured about 6 to 10 μ in diameter. They stained a peculiar bluish-red colour with Giemsa, and were quite readily distinguished from the very numerous cell granules present. When one-half of a Giemsa-stained film was treated with a drop or two of orange tannin (orange G 1, tannin 5, water 100) for a minute or two and then washed, these small masses were exceedingly well differentiated, and were totally unlike other granules. The groups consisted of fairly closely packed coccoid bodies, single, in pairs, or three or four together. Their outline is remarkably definite, and I find, from photomicrographs taken at a magnification of 2000 diameters, that they measure about 0.25 to 0.45 μ . Mr. Eliot Meriin, by very exact measurements, says that

he finds that the smallest range from 0.24 to 0.3 μ , but that many are somewhat larger. Not only are these clusters found free, but some are also seen in the interior of greatly swollen endothelial cells, and their sharp outline, somewhat regular size, and the peculiar staining reaction prevents confusion with the normal cell contents.

To my mind they very closely resemble some of the rickettsia bodies. I compared them with a slide of *Rickettsia prowazeki* of typhus fever in the louse, and they bore a striking similarity to the coccoid and paired coccoid stage of these bodies, but the colour was somewhat different, the rickettsias being bright red (possibly from the fading of the blue of the Giemsa stain, as the film was made in 1922).

The photomicrographs (see Figure) taken at a magnification of 1500 diameters are here reproduced at a magnification of about 2200, and show the distinctive features of the coccoid bodies in clusters from the spleen.

The question which naturally arises is: What is the nature of these organisms; are they accidental, commensal, or secondary invaders, or are they causal? Any speculation about their nature or relationship must be premature at this time, with such limited material at hand, and much more work must be undertaken before a definite expression of any opinion can be given as to the part they play in the causation of psittacosis. I am of the opinion that the small bacilli will prove to be secondary invaders, but that the coccoid and diplococcoid bodies found in the blood of man and infected animals are probably identical with the very characteristic and suggestive groups or masses of these bodies in the spleen of the inoculated mouse. The coccoid bodies are small enough to pass the Seitz filters and have been very definitely found in the filtrate, and these may prove to be the causal organisms of this obscure disease. They might provisionally be termed the coccoid X bodies of psittacosis.

I would here like to express my sincere thanks to Dr. Western for his kindness in sending me specimens.

CÆSAREAN SECTION UNDER SPINAL ANÆSTHESIA.*

By JOHN WILLIAM BURNS, M.D. DUB..

F.R.C.S. EDIN., F.B.C.O.G.,

HON. SURGEON TO THE LIVERPOOL MATERNITY HOSPITAL, AND TO THE LIVERPOOL AND SAMARITAN HOSPITAL FOR WOMEN.

THE obstetrician is always faced with a very difficult problem when called upon to deal with pregnancy and labour complicated by a serious cardiac lesion and weak or failing compensation. There is another type of case which causes considerable anxiety—the patient faced with a complicated labour, who is at the same time suffering from bronchitis or some other respiratory difficulty which would render a general anæsthetic risky. During the past two years I have performed Cæsaean section under spinal anæsthesia on ten patients; seven of these were suffering from advanced cardiac disease with failing compensation, one had severe bronchitis and malpresentation (flying foetus), and two were cases of contracted pelvis. It is extremely doubtful that any of the cardiac cases would have survived even a simple straightforward labour.

Technique.

No morphia or other sedative is given before the operation. The patient is placed upon the operating table lying on the right side with the knees drawn up and the back arched forwards. One of the lumbar spaces is chosen just above the level of the iliac

* Read before the North of England Obstetrical and Gynecological Society, April 11th, 1930.

crests. The needle is inserted into the skin just below the midline and on a level with the centre of the space between two lumbar spines. The needle is pushed forwards, inwards, and upwards. It is easier to find the spinal canal by this method than by placing the patient sitting upright. A 10 c.cm. syringe which has previously been charged with stovaine 1 c.cm. is then inserted into the spinal cannula, and an equal quantity of spinal fluid is withdrawn and mixed with the stovaine solution in the syringe. The mixture is then slowly injected. The preparation of stovaine which I use is the stovaine Billen (Chaput formula) put up by Messrs. May and Baker. With this preparation I have not had a failure. After the injection the patient is turned upon her back and the shoulders slightly elevated. Usually by the time the surgeon is ready to operate the patient is anæsthetic up to the costal margin.

The classical Cæsaean section was carried out in all cases and in all the anæsthesia was perfect. The outstanding feature of the operation was the small amount of blood lost by the patient, particularly on incising the uterus, except in those cases where the placenta was situated on the anterior wall. The uterus in all cases contracted very strongly and rapidly upon delivery of the infant. This hypertonic contraction of the uterus associated with spinal anæsthesia has also been noted by Metzger¹ who states that because of this spinal anæsthesia is not advisable for such obstetrical operations as the application of forceps or version.

Most of the patients midway through the operation complained of "feeling sick." Whether this was a symptom of falling blood pressure or to interference with the peritoneum I cannot say. The injection of 0.5 c.cm. pituitrin produces relief at once. Sensation begins to return in about one hour and a half and is complete in three to four hours. The first complaint is abdominal pain. There were no post-operative complications of any severity. Severe headache was noted in three cases which persisted for about twelve hours.

In cardiac cases operated upon it was noted that the operation had no appreciable effect upon the patient as far as one could tell from the pulse-rate. All the cases made good recoveries from the operation and were able to leave hospital at the end of three weeks. In all the cardiac cases compensation was to a certain extent restored—i.e., they could get about quietly, the orthopnoea and dyspnoea had disappeared, and they were able to nurse their babies without undue effort. It is a moot point whether these patients should be allowed to nurse the child or not. In my experience I have not found that nursing throws any special burden upon these patients' cardiac condition, I therefore encourage nursing for the first three or four weeks at least. As these patients' families are of necessity limited, it is very important that the infant should be launched upon the sea of life under the best possible circumstances. This can only be brought about by meeting its normal physiological needs in the early days of its existence.

The following is a short account of the cases operated upon:—

CASE 1.—Multigravida, aged 32. Five normal labours and one transverse. Condition on admission: severe bronchitis, cough, dyspnoea. Pregnancy: period 39 weeks; malposition of foetus (lying foetus) reported in THE LANCET, 1923, ii., 761. Termination of pregnancy: Cæsaean section. Intrathecal stovaine. Result: uneventful recovery. Abdominal pain two hours after operation, sensation complete in four hours. Lochia red to the tenth day. No headache. Discharged fit in 14 days.

CASE 2.—Primipara, aged 23. General condition good. Pregnancy: period full term; contracted pelvis with marked disproportion. Termination of pregnancy, Cæsaean section. Intrathecal stovaine. Result: uneventful recovery. No headache. Sensation complete in four hours. Discharged fit in 14 days.

CASE 3.—Aged 24, 2-para. One child, Cæsaean section at term. General condition good. Pregnancy: period full term; contracted pelvis with marked disproportion. Termination of pregnancy, Cæsaean section. Intrathecal

stovaine. Result: uneventful recovery. No headache. Sensation complete in 34 to 4 hours. Discharged fit in 14 days.

CASE 4.—Multigravida, aged 35. Three normal labours, one transverse. Rheumatic fever when 7 years old. Condition on admission: fainting attacks, dyspnoea, orthopnoea, pyrexia. Mitral stenosis with very poor compensation. Pregnancy: period on admission 35 weeks. Termination of pregnancy, Cæsaean section. Intrathecal stovaine in thirty-ninth week. Result: operation appeared to have very little effect upon the patient's cardiac condition. Slight nausea during operation. Sensation complete in four hours. Discharged fit on twenty-third day.

CASE 5.—Aged 42, 11-para. Nine normal labours and two miscarriages. Rheumatic fever when 31 years old. Condition on admission: very breathless and distressed, orthopnoea, cough, had had two attacks of epistaxis. Mitral stenosis and aortic regurgitation. Compensation poor. Pregnancy: period on admission 33 weeks. Termination of pregnancy, Cæsaean section. Intrathecal stovaine at term. Result: operation no effect on cardiac condition, pulse 76 at end of operation. Slight abdominal pain complained of four hours after operation. Sensation complete four hours, lochia red to the tenth day. Discharged fit on the seventeenth day.

CASE 6.—Primipara, aged 24. Has been in heart hospital for considerable time. Condition on admission: dyspnoea, orthopnoea, cough, mitral stenosis, very poor compensation. Pregnancy: period on admission 37 weeks. Termination of pregnancy: intrathecal stovaine in thirty-eighth week. Result: operation had no effect on pulse-rate. Abdominal pain complained of at end of three hours, sensation complete in four hours. Delusions on third day. Lochia red to tenth day. Good recovery. Discharged fit on twenty-first day. Nursing.

CASE 7.—Aged 24. Condition on admission: dyspnoea, orthopnoea, mitral stenosis, poor compensation. Pregnancy: period on admission 35 weeks. Termination of pregnancy: intrathecal stovaine at term. Result: good recovery from operation. Compensation slowly restored. Discharged fit and well in three weeks. Nursing baby.

CASE 8.—Aged 39. Condition on admission: rapid irregular pulse, dyspnoea, and orthopnoea; mitral stenosis, poor compensation. Pregnancy: period on admission 34 weeks. Termination of pregnancy, intrathecal stovaine near term. Result: good. Uneventful convalescence. Discharged from hospital in three weeks. Nursing baby.

CASE 9.—Aged 24, 2-para. One premature child and one miscarriage. Chorea when 14 years of age. Condition on admission: marked dyspnoea, orthopnoea, oedema of legs and vulva; rapid irregular pulse, some cyanosis. Later developed cough. Cardiac lesion: mitral stenosis and some regurgitation; very poor compensation. Period of pregnancy 30 weeks. Termination with intrathecal stovaine in thirty-eighth week. Result good. Pulse-rate not increased by operation. Uneventful recovery, except that chest was troublesome for about ten days. Compensation only very slowly recovered. Discharged on the twenty-first day fairly well and nursing child.

CASE 10.—Aged 29, 3-para. Two normal labours and one miscarriage. Condition on admission: dyspnoea, cough, cyanosis, and oedema of legs. Mitral stenosis, some auricular fibrillation, poor compensation. Period of pregnancy on admission about 22 weeks. Termination of pregnancy: intrathecal stovaine at term. Result: good pulse-rate not affected by operation. Convalescence complicated by the fact that the patient burst all her stitches on the fifth day by coughing. The abdomen was sutured without an anæsthetic. After this the patient made a good recovery. The chest symptoms slowly disappeared and compensation gradually restored. Severe headache was complained of on the second day. Discharged on the twenty-fourth day fairly well.

Conclusions.

Cæsaean section under spinal anæsthesia is an ideal method of dealing with pregnancy complicated by a serious cardiac lesion. The operation in my experience throws no strain upon the heart and in the seven cases dealt with in this note the evidence of shock resulting from the operation was completely absent.

As a method of terminating pregnancy in these cases it is much to be preferred to induction of premature labour or delivery by forceps. It is, in my opinion, very risky to allow a patient with a serious cardiac lesion and failing or poor compensation to undergo the stress of even a simple labour. An added advantage of Cæsaean section is that sterilisation can be carried out at the same time. This is important when the cardiac lesion is a serious one.

It is essential in dealing with these cases that the cardiologist and the obstetrician should work together.

¹ Metzger: Rev. Franç. de Gyn. et d'Obst., January, 1929.

I have been most fortunate in having the enthusiastic help of Dr. John Hay and Dr. Wallace Jones. I am greatly indebted to them for the way in which they have supervised the treatment of the patients while in hospital or rest home.

PROOF OF PATENCY OF A COMMON BILE-DUCT

BY INJECTION OF LIPIODOL.

By W. B. GABRIEL, M.S. LOND., F.R.C.S. ENG.,
SURGEON TO THE ROYAL NORTHERN HOSPITAL; SENIOR ASSISTANT
SURGEON TO ST. MARK'S HOSPITAL FOR DISEASES
OF THE RECTUM.

DRAINAGE of the common bile-duct after its incision for removal of a stone is now the universally accepted practice. The advantage, in certain cases, of prolonged drainage by the use of a T-tube has been

called in her doctor, Dr. W. C. B. Meyer, for the first time on Feb. 7th, and I saw her in consultation the same day. She then had had severe vomiting for three days, her bowels had not been open since Feb. 2nd, and an enema had been returned clear. Her temperature was 101.6° F. and the pulse-rate 120. Abdominal examination revealed a large tender mass in the right upper abdomen suggestive of an acutely inflamed gall-bladder. In view of the possibility of an intestinal obstruction I advised immediate laparotomy and the patient was transferred to the Royal Northern Hospital.

*First operation (cholecystostomy, Feb. 7th).—*An incision over the mass revealed a large acutely inflamed gall-bladder with adherent omentum, and flakes of lymph on its surface. The patient's general condition was very bad and her pulse-rate went up to 170 on the table. A cholecystectomy was therefore considered to be inadvisable, and I completed the operation rapidly by emptying the distended gall-bladder of a large amount of foul-smelling pus with a trocar and cannula and stitching in a large-sized de Pezzer catheter with the end cut off. She made a good recovery. The tube was removed on the tenth day after operation. The wound was healing well without any biliary leak until Feb. 27th when she had an attack of vomiting and a copious discharge of bile appeared from the sinus in the abdominal wall.

FIG. 1.

FIG. 2.

FIG. 3.

Showing the T-tube in position in the common bile-duct 19 days after operation.

Taken immediately after injection of lipiodol into the tube; the opaque solution has reached the duodenum without delay.

Taken a minute later, showing the left and right hepatic ducts outlined and general diffusion of lipiodol throughout the small intestine.

pointed out by Judd and White.¹ The tube can be left in situ for many months if necessary and permits of a free exit of bile. If any serious degree of cholangitis or pancreatitis is present the prolonged rest is very beneficial, and if there is any debris or biliary mud in the common bile-duct regular lavage with saline is easily carried out. When the time for removal of the tube draws near it may be clamped for a number of hours and the effect on the patient observed; if no discomfort results the presumption is that bile is flowing down freely through the short limb of the T-tube.

A recent paper by Ginzburg and Benjamin² entitled *Lipiodol Studies of Post-operative Biliary Fistulae* suggested to me that with a T-tube in the common duct the patency of the duct might readily be proved by injection of lipiodol before removal of the tube.

A married woman, aged 45, had an operation for acute appendicitis in India during 1926. Later she had a residual pelvic abscess which had to be drained, and in 1927 she had an attack of jaundice.

On Feb. 2nd, 1930, an attack of acute abdominal pain began; it was localised chiefly to the right upper quadrant and was accompanied by obstinate constipation. She

A profuse biliary leak continued and her stools became clay-coloured. An X ray did not reveal a calculus but obstruction of the common bile-duct by a calculus appeared probable.

*Second operation (March 14th).—*I explored the biliary passages through a transverse incision after infiltration of the abdominal wall with percaïn solution 1 in 1000. A large solitary oval stone was milked up from the lower part of the common bile-duct and was removed after incising the common duct over it. A cholecystectomy was then performed and the common duct drained by insertion into it of a Kehr's T-tube. Subsequent progress was uneventful. Bile drained freely from the tube which was washed through with saline solution every four hours. On March 21st it was clipped for an hour morning and evening. This caused no discomfort and the clip was gradually applied for longer intervals up to three hours twice daily.

On April 2nd the accompanying radiograms were taken. Fig. 1 shows the tube in position. Lipiodol was then injected and the radiogram shown in Fig. 2 was taken as soon as the lipiodol was seen on screen examination to have reached the common duct. It reached the duodenum very rapidly and proved that there was no obstruction in the distal part of the common duct. The radiogram seen in Fig. 3 was taken about one minute later and shows the left and right hepatic ducts outlined and general diffusion of the lipiodol through the upper loops of the small intestine. On the 4th the tube was clamped continuously for 48 hours without causing any symptoms

and was removed by gentle traction on the 10th after preliminary injection of morphia and scopolamine. The biliary fistula was closed in 24 hours and the patient is now convalescent; she is free from symptoms, her stools are of normal colour, and her complexion is clear.

Clinical and Laboratory Notes.

TWO CASES OF INTESTINAL DISEASE IN INFANCY.

BY ANNE E. SOMERFORD, M.D. MANCH., D.P.H.,

PATHOLOGIST TO THE ROYAL MANCHESTER CHILDREN'S HOSPITAL
PENDLEBURY.

THE two following cases of intestinal disease in infancy appeared to be worthy of record, owing, in one case to the rarity of the condition at such an early age, and in the other to the clinical signs and symptoms.

Perforation of a Duodenal Ulcer in a Child of 14 Days.

The patient was a full-time male child (labour and delivery had been normal) who at the age of 12 days began to vomit all his feeds, the vomit being projectile in type, while the bowels became confined. Two days later he was brought to the out-patient department of the Royal Manchester Children's Hospital and was admitted once as an in-patient, but died a few hours after admission. While in hospital he vomited continuously, the vomit consisting of a deep orange-coloured fluid, evidently containing bile. It was not, unfortunately, examined for blood. The abdomen was very distended but visible peristalsis was not seen.

At the autopsy the following condition was found. The child was an emaciated infant and the abdomen was much distended. The chest contents were normal. The peritoneal cavity was found to be filled with orange-coloured faeces which had even penetrated to the posterior surface of the liver. There was a small, round perforation on the anterior surface of the duodenum one centimetre beyond the pylorus. This perforation was about three millimetres in diameter and faeces were oozing through it. In spite of gentle handling the aperture rapidly increased in size, as though the surrounding wall were very friable. To the naked eye the duodenal wall appeared to be normal and sections also failed to reveal any abnormality. The stomach, pylorus, and the rest of the small intestine were normal. The caecum was much dilated and filled with fairly solid faeces. The ascending and transverse colon were normal. In the descending colon there was a narrowed portion about two centimetres in length, but faecal material could easily be squeezed through it. The liver, kidneys, spleen, and pancreas were normal. In the mesentery were numerous small bodies varying up to the size of a hazel nut. They were rounded and pale pink in colour and on section proved to be fibromyomata. The skull presented a suture about 1.5 cm. in width, passing across the frontal bone and reaching almost to the bridge of the nose, and there was much bossing of the frontal bone. The lower jaw was unduly prominent.

Congenital Diverticulum of the Jejunum.

A male child, aged 2 months, was admitted to the Royal Manchester Children's Hospital, Pendlebury, on Sept. 30th, 1929, with a history of vomiting abdominal pain, and melaena of two months' duration. Examination revealed extreme pallor of the mucosa and yellowish discoloration of the skin surface generally. The liver was just palpable, but there were no other physical signs. A blood count showed a severe anaemia of a secondary type (red cells, 1,752,000; haemoglobin less than 20 per cent.; leucocytes, 10,800). During his stay in hospital he vomited once daily, and the stools, with one exception, contained occult blood. On Oct. 12th, 1929, a subcutaneous injection of citrated maternal blood was given into each axilla, but death took place three days later.

At autopsy the child was well formed, rather fat, and extremely pale. The heart and lungs were almost colourless. The liver and kidneys were pale, and the spleen was enlarged and pulpy. A very careful scrutiny of the stomach and intestinal tract failed to reveal the presence of any ulcer or bleeding point. Arising from the jejunum on the mesenteric side was a sac measuring 9.75 cm. in length by 4.6 cm. in width. It was attached along its entire length to the jejunum

with which it communicated at the proximal end by an opening 2 cm. in diameter. The distal extremity of the sac was blind and was filled with dark-coloured faecal material. Sections were not made of the sac wall, but to the naked eye it resembled the small intestine. There was no apparent bleeding point or ulceration within the sac, but as proximal to the mouth of the sac the intestinal contents were pale yellow, and distally they were dark, it appeared that the sac was responsible for the haemorrhage.

Moynihan¹ collected 13 cases of duodenal ulcer in infants between 6 weeks and 10 months of age. Rogers² reported two cases of duodenal ulcer occurring in infants of the same family, but without perforation. Thelle³ collected 264 cases of gastro-duodenal ulceration of which 58 per cent. were duodenal in type. I have failed, however, to find any record of a perforation occurring at such an early age.

I wish to thank Dr. C. P. Lapage and Dr. J. F. Ward for their kind permission to publish the clinical notes of these cases.

LOCAL ABSORPTION OF FAT DUE TO INJECTIONS OF INSULIN.

BY L. R. WOODHOUSE PRICE, B.A. CAMB.,
M.R.C.S. ENG.

Local atrophy of fat following the prolonged treatment of diabetes mellitus by injections of insulin has been described by Avery,¹ Rabinowitch,² and Graham and Carmichael,³ but hitherto no account of the post-mortem appearances has been published.

The opportunity arose in the case of a woman aged 34 years who was admitted to St. Bartholomew's Hospital on Nov. 2nd, 1928, in coma. She developed diabetes mellitus in 1924, and was successfully treated as an out-patient by injections of insulin in doses varying from 5 to 20 to 20+20 units per day for four months. Thereafter the treatment was continued by the self-administration of insulin and she progressed satisfactorily up to a few days before her admission. She suddenly became comatose and died in spite of adequate insulin treatment.

Post mortem a depressed area was found on the anterior surface of each thigh, in the region of the apex of Scarpa's triangle. This area was about two inches in diameter in each case. A section of the tissues of one thigh was removed, about half an inch in thickness. Macroscopically (see Figure) it shows the absence of subcutaneous fat over a limited local area. The overlying skin is rather whiter than usual, and its surface is slightly depressed. No gross pathological change is evident in the skin or in the muscle of the thigh. Microscopically, the structure of the skin is unchanged. In one part of the section there is no fat intervening between the skin and the muscle, the connective tissue having the appearance of being condensed. No cellular infiltration or indication of inflammatory reaction is apparent.

It is not known for certain that the patient injected the insulin at these sites, for the condition was discovered only after death. The specimen has been preserved in Kaiserling's solution.

I wish to thank Prof. F. R. Fraser, who had charge

Sketch of skin and subcutaneous tissue showing absence of fat over a limited area.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF UROLOGY.

At a meeting of this Section held on April 30th, Mr. FRANK JEANS, the President, being in the chair, Prof. HUGH YOUNG (Johns Hopkins University, U.S.A.) gave an address on the advantages of

THE PERINEAL ROUTE

in the treatment of various diseases of the prostate. It was not his purpose, he said, to persuade his hearers that perineal prostatectomy was superior to suprapubic—Sir Peter Freyer and his associates had done so much to show its value. But owing to the success which urologists in England had had with the suprapubic route, it was perhaps not sufficiently appreciated that the perineal route could well be employed for other pathological conditions of the prostate. One reason for the unpopularity of the perineal route in early days was the use of the median incision, the operator plunging his knife through the perineum, cutting through the bulb, with consequent free bleeding, through the triangular ligament, through the external sphincter, and if he were not careful, incising rectum or bladder, when not only serious hæmorrhage but incontinence resulted. Early perineal prostatectomists such as Goodfellow tore or cut through these structures; Charles Mayo devised a method of enucleating parts of the lobes; and consequently perineal prostatectomy came to be associated with a risk of damage and hæmorrhage, and also of incontinence and disturbance of the sexual function owing to interference with the ejaculatory ducts and other delicate structures. In reaching the prostate, his hearers knew the importance of avoiding those structures which early urologists so frequently injured. It was necessary to cut at the back of the bulb and the two transverse perineal muscles, so as not to injure the sphincter. Two layers of fascia seemed to have been put there by Nature to protect adjacent structures; they shielded the rectum from infection, and caused malignant disease to pass upwards instead of through the rectum. As the prostate increased in size the urethra became flattened from side to side, while the middle lobe extended through the sphincter into the bladder, causing obstruction there and giving rise to hypertrophy of the trigone.

One advantage of operating on the prostate through the perineum was the ready production of local anæsthesia by a single injection through the sacral canal. Difficulty if it occurred was due to the patient's position. If a flat table was used no adequate view could be obtained of the field of operation. He showed on the screen a picture of the special table he used; good results, however, could be obtained on an ordinary table by means of sandbags and straps. At a later date the median incision was replaced by an oblique incision to one side, which was found safer and caused less hæmorrhage. It also brought the operator straight into the apex of the prostate, without destroying important structures. Even to-day few surgeons could show a better series of results than some operators had with this method. The operation

was based on the triangular ligament and the ischio-pubic ramus. After the primary incision the surgeon used blunt dissection on each side of the median raphe, avoiding injury to the transverse perineal muscle. The central tendon was brought into view by means of a bifid retractor. In most cases the prostate was brought out, so that the operator could see what he was doing. It should be palpated and the diagnosis confirmed before proceeding. If the case was one of prostatic hypertrophy, the enlargement could be extracted through a variety of incisions. The median incision would give the same result as the suprapubic; or the incision might be peri-lobular, or bilateral, or in the form of an inverted "V." He had tried every kind and was not yet satisfied as to which was best; the "V" incision opened the part up and made it easy to enter and enucleate the two lateral lobes. Scissors could be used if care was taken to do no injury to tissues which were not pathological and which were to be left behind. In many cases it was possible to follow the aberrant lobules beneath the trigone and to remove them in one piece with the lateral lobes.

Where a previous cystoscopy had showed the presence of hypertrophied tissue in the anterior commissure or the anterior lobe it was desirable to remove the commissure also. That gave the sort of specimen which Freyer nearly always obtained; he broke through the mucous membrane and enucleated the pathological prostate from the outside of its encapsulated fibres, nearly always removing a portion of the anterior commissure and the anterior part of the urethra with it. It could be done in that way through the perineum if the surgeon started from the outside and went round as Freyer did, removing the hypertrophied prostate in one piece. Most American surgeons who practised suprapubic prostatectomy went through the urethra and did not remove the anterior commissure. If the patient had a very large middle lobe, much less tissue was dragged through the sphincter in the perineal operation.

In the majority of cases, said Dr. Young, he used the bilateral incision, the objection to which was that the hypertrophied tissues or lobes could not be removed in one piece. It was more conservative than the inverted "V," as there was less injury to the urethra; the first cases he did by this method healed up more quickly, and there was less disturbance of the sexual function than in other cases. But there was also less chance of inspection and of being sure that the tissue to be removed had all been taken away. This procedure was advisable for cases of carcinoma which had gone too far to permit of radical operation. In a fair proportion of cases when operating through the perineum the surgeon encountered calculi lying external to the hypertrophied portions and beneath the normal prostate. If such a calculus was beneath the middle lobe, it could be removed through the lateral incision. He had practically never been able to appreciate or remove calculi by suprapubic prostatectomy when they were in that portion of the prostate. Having removed prostate and stone, through an inverted "V" incision, the surgeon was in a position to carry out whatever might be desirable. His present method was, after removing the prostate, to push into the bladder a rubber bag which was then blown up with air or water so as to form a tractor to stop hæmorrhage; a tube in the centre of the bag allowed for drainage. That obviated the need for gauze packing or sutures. But the wound took longer to close, and convalescence was slower.

Causes of Mortality.

Of the immediate causes of death in these cases, the more important were pneumonia and pulmonary embolism. His own mortality-rate, in 1571 cases, was 3.6 per cent. The most serious post-operative complication was embolism which might take place as late as three to six weeks after the operation. It was not known exactly why it occurred, but there was such a risk in all operations below the umbilicus

A careful comparative study by the surgical department at Johns Hopkins Hospital had shown that pulmonary embolism was now more common all over the world than formerly. This was also the view at the Mayo Clinic. Sometimes no lesion was found in the femoral vein, yet in the heart there was a long clot which must have come from it. Possibly posture had something to do with the formation of emboli; certainly sepsis played an important part. Only 8 per cent. of the fatal cases in his series could be attributed to the heart condition. The variation in mortality-rate over 20 years was interesting. At first the operative mortality was 84 per cent.; in the next 60 cases it came down to 5 per cent.; and in the following two years to zero—96 operations without a death. The publication of these results, and the consequent receipt of extreme cases from many places—possibly combined with a little over-confidence—caused the mortality to return to 5 per cent. Again the zero point was reached, and after the war there was another rise. During the last three years, operations including men over 80 years of age, he had had no deaths. It was fair to conclude that the operation per se need not be regarded as a serious one; but in patients of prostatectomy age, any pathological condition might be met with, and there was always necessarily some risk. Not infrequently the vesical orifice was in a condition of fibrosis, especially difficult to remove by the perineal route.

Hypertrophy and Malignancy.

Twenty-two per cent. of men who came to his clinic with symptoms of prostatism had carcinoma, and in many the malignancy was contemporaneous with hypertrophy. Osler had well said that the general practitioner should make himself as adept at examining the prostate per rectum as he was at examining the lungs, and that this examination should be done more frequently. Medical men should be impressed more than they were with what could be gained by early operation in these cases. Too often, by the time the patient reached the urologist the lateral lobes as well as the seminal vesicles were indurated, and there was little hope of a radical cure. In 50 per cent. of cases of carcinoma in his experience there were two lateral hypertrophies and a carcinoma at the back; there seemed, indeed, to be a selective affinity between carcinoma and hypertrophy. Carcinoma, almost in every case, developed in the posterior portion. The cystoscope showed great lobes projecting into the bladder, and the surgeon must not be deceived into supposing that there was present no more than ordinary hypertrophy. He had found that in practically all cases in which there were grounds for suspecting carcinoma, the suspicion proved justified. In suspicious cases the prostate should be exposed, resected, and a frozen section made.

In cases in which the disease had progressed so far that radical operation was impossible, as a rule no operation was needed, because these men were able to urinate. But something had to be done on account of complete retention, a catheter life was apt to prove difficult and painful, and there might be much bleeding. His practice then was to resect the lateral and median portions of the prostate sufficiently to remove the obstruction. He and his colleagues had dealt with about 400 cases in this way, and the majority had continued able to pass water. The procedure had not stayed the onset of the carcinoma, but had given the patients a more comfortable existence than followed simple suprapubic drainage. The perineal route was justified in cases of diverticulum of the posterior urethra which appeared on the surface and the opening of which could be found by means of the cysto-urethroscope. Another condition which urgently required perineal prostatic surgery was the trauma to the posterior urethra, generally at the junction of prostatic and membranous portions, which occurred in fractured pelvis. Recto-urethral fissure also was operable through the perineum. For septicæmic conditions he relied on the intravenous

use of arseobenzol or mercurochrome, 25 to 30 c.cm. of a 1 per cent. solution of the latter.

The PRESIDENT thanked Dr. Young for his address, which was illustrated by a large series of lantern slides. There was no discussion.

SECTION OF ANÆSTHETICS.

Mr. R. E. APPERLY, the President, took the chair at the annual general meeting of this Section on May 2nd. After officers had been elected and other business transacted, a paper on

ETHYLENE ANÆSTHESIA

was read by Dr. R. J. CLAUSEN. Ethylene as an anæsthetic had been first mentioned, he said, in 1849 by Thomas Nunnely, a surgeon of Leeds, who had condemned it on several grounds. Its modern use dated from 1923, when Luckhardt, of Chicago, and other transatlantic workers had applied it successfully. It had attained popularity in America and Canada, but not in this country. Dr. H. P. Fairlie, of Glasgow, had, however, had considerable experience, and Sir Francis Shipway and Dr. C. Langton Hewer had both reported favourably on it in 1925. Its formula was C_2H_4 ; it had no colour but a characteristic and unpleasant smell, part of which might be due to impurities. It was highly inflammable and when mixed with oxygen, air, or nitrous oxide, explosive. It could be used in a McKesson or any other good machine calibrated for nitrous oxide; the oxygen percentage given was theoretically less than with nitrous oxide but actually was unexpectedly large. The cylinders were similar in size but only contained 150 gallons of ethylene as against 200 gallons of nitrous oxide. The valve nozzles had a left-hand thread as a warning of the inflammability of the gas, and therefore required special adaptors in a Boyle's machine; Dr. Clausen preferred the yoke attachment with straight or type 7 valves. He had given 371 administrations, 92 of which had been for dental extraction and the remainder mostly for gynaecological operations. The McKesson apparatus had been employed for practically all. Ages had ranged between zero (represented by five Cesarean sections) and 84; the longest anæsthesia had lasted 2 hours 25 minutes. Ethylene had proved excellent in pelvic operations in combination with spinal anæsthesia. A few endotracheal applications had been given. The preparation and premedication had followed the ordinary hospital routine; some hypnotic was desirable, and Dr. Clausen recommended gr. 1/6 morphia with gr. 1/100 atropine.

Induction was quick and pleasant, and followed the same technique as with nitrous oxide. It was generally commenced with nearly pure gas, the oxygen percentage being increased slightly after the first few breaths. If the breath were suspended through secondary saturation, pure oxygen would quickly restore it. The time of induction was probably less than with nitrous oxide, and the onset of anæsthesia was quick and sudden with relaxation. The type of anæsthesia was like that produced by nitrous oxide but was deeper and smoother; there was more relaxation and the pulse- and respiration-rates were slower. The oxygen percentage being higher, the colour was deeper, but the signs of anoxæmia were not usually so obvious. The oxygen percentage ranged from fifteen to thirty, the dial showing 10-15 per cent. The consumption of gas averaged about 60 gallons an hour, and of the oxygen about two cubic feet; in hospital this would cost about 3s. 3d.

Either had been given as well in nearly all abdominal operations to secure adequate relaxation, but could probably be dispensed with if heavier premedication were used and the induction prolonged. It was more effective with ethylene than with nitrous oxide, and an average of two and a half ounces had been sufficient in a series of operations lasting on an average

82 minutes. It was chiefly useful for debilitated and shocked patients, in the repeated anaesthetics of radium therapy of the uterus, and in hospital dental work.

Recovery from ethylene was nearly as quick as from nitrous oxide, though complete elimination of the gas took much longer. It was succeeded by a long period of analgesia. The patient's condition after a long anaesthesia was strikingly good, and convalescence was equal to that after nitrous oxide. Slight vomiting was common after applications lasting more than a quarter of an hour, but serious sickness was rare, though more frequent than with nitrous oxide. No deaths could be attributed to ethylene, though it had been blamed for the death of one Cæsarean baby with unexpanded lungs.

Its drawbacks were (1) its smell; (2) increased hæmorrhage; (3) risk of fire. The smell could be counteracted by the use of an efficient exhaust pipe; Dr. Clausen used a rubber hose-pipe of about half an inch bore, which could be carried in his case. In hospital a permanent exhaust pipe could be fitted with little trouble. This device produced no ill-effects in the patient, as it only caused a respiratory pressure in the mask of at most half a millimetre of mercury. Another means was a closed circuit with carbon dioxide absorption. Hæmorrhage was not much increased, and some patients bled profusely with other anaesthetics. The risk of fire or explosion was real, and ethylene should not be used near naked lights, cauteries, diathermy, or other sources of heat. Most of the reported accidents seemed to have been due to neglect or to static electricity, a phenomenon rare in this country. There was little risk of explosion with 20 per cent. of oxygen or less. Dr. Clausen only took one precaution, that of putting a little water into the rebreathing bag in order to moisten the mixed gases. To sum up, ethylene might often replace nitrous oxide with benefit, but its drawbacks at present prevented its general use, though it deserved a thorough investigation and trial.

Discussion.

Dr. LANGTON HEWER said that he had found the advantages of ethylene over nitrous oxide to be the deeper relaxation it gave and the higher percentage of oxygen that could be administered. In the laboratory ethylene hardly smelt at all, but when kept for 24 hours it acquired its characteristic acetylene-like smell, which must be due to impurities. If chemists could remove this disadvantage, the use of ethylene would be less unpleasant and might increase. The patient was hardly affected at all. The closed circuit had the drawback that it was difficult to see when the compound in the carbon dioxide filter had become used up, and a rather large container was necessary for a long case. He doubted whether ethylene had any advantages over nitrous oxide with a minimum amount of ether.

Dr. JOSEPH BLOMFIELD had formed a favourable opinion of ethylene from using it on a number of very sick patients in short operations. He had, however, abandoned it because of its detestable smell.

Dr. H. W. FEATHERSTONE asked how long the flexible expiratory tube must be. To move the table towards the window in a modern theatre would introduce complications, and a tube of any length caused back pressure. The smell was the greatest obstacle to anaesthetists who believed in the gas, for it intensified the criticism always levelled at a new method.

Dr. I. W. MAGILL did not regard ethylene as vastly superior to nitrous oxide. He suggested that the exhaust pipe be fitted with a suction motor to obviate back pressure.

Dr. ASHLEY DALY suggested that the death of the baby delivered by Cæsarean section had been probably due to the morphia of the premedication. He objected to a preliminary hypnotic for these operations.

Dr. CLAUSEN, in reply, said that this patient had not had morphia. He used a pipe about five yards long, which led into a corner of the theatre. The increase in back pressure was inconsiderable under ordinary conditions; it was only apt to be at all serious if the patient were straining or coughing or breathing deeply and violently. The smell was chiefly in evidence in dental work, where the exhaust pipe might not be practicable. The percentage purity of the gas was already 99.8, but the manufacturers were experimenting with a view to reducing the smell. Ethylene with a little ether gave better results than nitrous oxide with a fair amount of ether, and there was a definite balance in favour of ethylene.

Reviews and Notices of Books.

MEDICINE IN THE TROPICS.

Recent Advances in Tropical Medicine. Second edition. By Sir LEONARD ROGERS, C.I.E., F.R.C.P., F.R.S., Physician and Lecturer, London School of Tropical Medicine. London: J. and A. Churchill. 1929. Pp. 439. 12s. 6d.

In the preface to the first edition of this book Sir Leonard Rogers spoke of the detailed progress in tropical medicine of late years, as opposed to the giant strides of two or three decades ago. The second edition carries us a little further in this gradual advance, but contains no momentous additions. In the new edition a certain amount of material has been omitted to make room for sections on Oroya fever, verruga peruana, helminthic infections, granuloma inguinale, and climatic bubo; additions have also been made to the excellent illustrations. The section on Oroya fever and verruga peruana gives an interesting summary of H. Noguchi's research which has established the identical origin of the two diseases. Working with the *Bartonella bacilliformis* from the blood of a Peruvian case of Oroya fever, he found that he was able to produce both intermittent fever of the Oroya type by intravenous injection, and skin nodules typical of verruga by intradermal inoculation. He found that transmission occurred by the bite of a tick, which explains a local belief that the disease is only contracted by those sleeping in affected areas, and cannot be acquired during a visit in the daytime. No satisfactory treatment of the two modifications of the disease has been found, but salvarsan appears to be of benefit. Sir Leonard Rogers deals with the common tropical diseases in the way which is most likely to be of value to the practitioner who has to handle them—that is to say, he gives prominence to treatment and to those practical points in diagnosis which can be distinguished by an isolated physician in the tropics. Detailed descriptions of laboratory technique are avoided.

The Care of Children in the Tropics. By ERIC C. SPAAR, M.D., M.R.C.P., Physician, General Hospital, Colombo. London: Baillière, Tindall and Cox. 1930. Pp. 265. 7s. 6d.

THIS book is intended for the use of mothers and young practitioners, and comprises a well-arranged and readable account of the essentials of paediatrics, with special information on problems peculiar to tropical climates. A chapter which will be particularly helpful to mothers who are unfamiliar with such climates is one on nursery hygiene, containing details of the management both of the baby and the ayah. Considerable attention is devoted to infant feeding, and due stress is laid on the additional importance of breast-feeding under unfavourable hygienic and climatic conditions. In artificial feeding the relative merits of fresh and dried milks have to be considered on quite a different basis to that which arises in England, and, except under special circumstances, the use of dried milks is here advocated. This book

should be a wise investment for any parent who is faced with the problem of bringing up children in a hot country.

Epidemiology and Control of Malaria in Palestine. By ISRAEL J. KLIGLER, Director, Department of Hygiene, Hebrew University, Jerusalem. Chicago: University of Chicago Press. 1930. Pp. 240. 22s. 6d.

THIS is an extremely well-planned piece of work which is a testimony to the care and industry of Dr. Kligler. Although primarily of local interest, the book contains evidence of extensive personal observation and may be widely read on that account. The chief carrier of malaria in Palestine is known as *Anopheles clutis*, and all the efforts designed to keep it under control are adequately reviewed in this book.

Malarial Nephritis. Epidemiological and Clinical Notes on Malaria, Blackwater Fever, Albuminuria, and Nephritis in the Interior of British Guiana Based on Seven Years' Continual Observation. By GEORGE GIGLIOLI, M.D. Italy, D.T.M. & H. Eng., Chief Medical Officer to the Demerara Bauxite Co., Ltd., British Guiana. London: J. and A. Churchill. 1930. Pp. 164. 8s. 6d.

THE high incidence and severity of nephritis in the tropics, especially in South America, has given rise to considerable concern and speculation. It has formed the subject of several inquiries and has been widely discussed in recent papers. Dr. George Giglioli, who is well known for his intensive and accurate work at Mackenzie City, has done well to combine in this small book his views on the relation of chronic malaria to nephritis together with his observations on the epidemiology of malaria and blackwater fever in British Guiana. Chronic nephritis, he finds, is not associated with any particular species of malaria parasite. Albuminuria was present in 25 per cent. of 550 cases examined. In benign tertian and quartan malaria the frequency of albuminuria increases with the duration of the infection and its tendency to relapse. In most old-standing cases of malarial nephritis the search for parasites in the blood may be negative. During seven years' observation in British Guiana 50 cases of blackwater fever were observed by Dr. Giglioli, and of these 33 occurred in children below 15 years of age.

The Mosquitoes of North America. By R. MATHESON, Professor of Entomology, New York State College of Agriculture, Cornell University. London: Baillière, Tindall and Cox. 1930. Pp. 268. 25s.

THIS is a modest but practical book. The author acknowledges his indebtedness to Howard, Dyar, and Knab for their masterly work on the mosquitoes of North and Central America. His own work has the merit of brevity and clearness. The keys of genera are well arranged and the descriptions of species adequate. Only eight species of anophelines are known from North America and several of these are rare, local, or confined to the more southern parts of the United States. Of culicines nearly 120 species are treated and described. The volume closes with nine plates illustrating the hypopygia as a means of differentiation. There are also numerous outline figures of the larvæ and a good index. Altogether a most useful work for students.

STATISTICAL METHODS FOR RESEARCH WORKERS.

By R. A. FISHER, Sc.D., F.R.S. Third edition, revised and enlarged. London: Oliver and Boyd. Pp. 383. 15s.

THE statistical problems which nowadays present themselves to the laboratory worker tend to increase in number rapidly, so that it is not surprising that Dr. Fisher's monograph should have reached a third edition within five years. The intention is that use should be made of the book without entering

into the mathematical theory of statistical methods, and the methods are here presented in the form of practical procedures, appropriate to the data with which the pieces of research work are actually concerned. None the less a very considerable familiarity with mathematical technique is required for the comprehension of the teaching. Few individual workers in the solution of medical problems are likely to possess the necessary equipment, but it is to the advanced biologist that the manual is directed. He will find the work valuable and the tables at the end to afford convenient assistance.

PATHOGENIC MICRO-ORGANISMS.

Ninth edition. By WILLIAM HALLOCK PARK, M.D., Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College, and Director of the Bureau of Laboratories of the Department of Health, New York City; and ANNA WESELS WILLIAMS, M.D., and CHARLES KRUMWIEDE, Asst. Directors of the Bureau. London: Baillière, Tindall and Cox. 1929. Pp. 819. 30s.

THE new edition of this well-known American text-book has been extensively revised. Its matter has been rearranged so that the grouping of the different micro-organisms conforms more closely to the classification adopted by the Society of American Bacteriologists, whose nomenclature has been adopted, though not to the exclusion of the older and more familiar terms. The chapters on the pyogenic cocci, the paratyphoid bacilli and the pneumococci have been practically rewritten. The consideration of the salmonellas is rather scanty and hardly up to the standard expected in this country, whilst a serious omission is the absence of discussion of somatic and flagellar antigens which makes the chapter upon agglutination decidedly out of date. A number of minor errors deserve attention—e.g., the description of the *Streptococcus fecalis* as a "viridans" organism on page 317; the quantity of serum to be injected intracutaneously in the Schultz-Charlton test is given as 1.0 c.cm. instead of 0.1 c.cm. (p. 329); and Nakayama's description of the process of obtaining fresh active leucocytes (p. 322) is incomprehensible. No mention is made anywhere of rheumatic fever. The book is, on the whole, well balanced and in spite of the increasing collaboration which has gone to its making it preserves much of that personal touch which has contributed so largely to its success.

CLINICAL ATLAS OF BLOOD DISEASES.

By A. PINEY, M.D., M.R.C.P., Research Pathologist, Cancer Hospital, London; and STANLEY WYARD, M.D., M.R.C.P., Physician, Bellingbroke Hospital. London: J. and A. Churchill. 1930. Pp. 99. 12s. 6d.

THE value of atlases of the blood is open to question. Given an acquaintance with the general principles of pathology and more particularly of the embryology and morphology of the blood, it is possible to make some sort of an intelligent deduction as to the type of blood picture to be expected in any particular pathological condition. For those, however, who have not mastered, or have no aptitude for, general principles, pictorial representation undoubtedly has its value. Thanks to the skill of Mr. J. R. Ford the present volume contains some of the best pictures of blood cells, both normal and abnormal, ever published. The accompanying text is skilfully arranged so as to give in the shortest possible space the outline of the pathology and treatment of the conditions considered. In future issues the authors might place a short descriptive caption below all instead of only below some of the plates.

The book is essentially one for the learner, and could hardly be bettered.

A MANUAL OF ZOOLOGY.

Sixth edition. By L. A. BORRADAILE, Sc.D., Fellow and Tutor of Selwyn College, Cambridge, and Lecturer in Zoology. London: Humphrey Milford, Oxford University Press. 1930. Pp. 683. 16s.

THIS book has primarily been written for university students starting zoology. It is deceptively small and contains an immense amount of reading matter with numerous illustrations. The first chapter is an introduction to the living organism in which the author endeavours to give, in an elementary form, the principles of metabolism and the biochemistry of life. Differences between the animal and vegetable kingdoms are also dealt with. The next four chapters are devoted to the anatomy, histology, and physiology of the frog. The subjects are dealt with simultaneously and in some detail, yet very concisely. In fact, the matter is so condensed that a beginner might hardly be able to cope with the material put before him. The protozoa are then described; the amoeba, paramecium, and vorticella receiving the most attention. There follows a chapter on protozoa pathogenic to man, the transmitting agents being briefly mentioned. The various phyla of the metazoa are then considered systematically, representative members being described in each case. In connexion with the nematodes, parasitism receives special consideration. Following upon the systematic zoology is an introduction to embryology, a classification of the animal kingdom, and an introduction to evolution. The final chapter is an introduction to animal ecology. The book concludes with an appendix indicating a course of practical training.

The book should be of value to university students doing first and even second year zoology. In particular it should appeal to medical students, for references to pathogenicity are abundant.

THE FEMALE SEX HORMONE.

By R. T. FRANK, A.M., M.D., Gynecologist to Mount Sinai Hospital, New York. London: Baillière, Tindall and Cox. With 86 figures in the text. Pp. 321. 25s.

THIS monograph differs from another upon the same subject by A. S. Parkes recently reviewed in THE LANCET mainly because the author is primarily interested in the clinical aspects of gynecology: an attitude which will commend itself to many of our readers. Unfortunately, however, the clinical side is also in many respects the more elusive, depending as it often does upon subjective evidence, and therefore needing even greater care and caution in its presentation. These virtues are not particularly noticeable in this monograph, either in the first part dealing with the biology, pharmacology, and chemistry, or in the second part concerning clinical investigations based on Dr. Frank's test for the hormone in the blood; many statements are made with a confidence which the reader may not share. Considering his 25 years of laboratory and clinical research Dr. Frank's own work may reasonably be expected to fill a considerable part of this volume; but the personal element may seem a little too prominent for a book which has the external appearance of a general survey of the subject. Statements based upon personal experience only, and even contrary to generally accepted opinion, are put forward without reference to opposing views. For example, the criticism of the water-soluble forms of the female sex hormone that "the rapid deterioration of such solutions bars their effective clinical use" is mainly based upon the author's tests of a number of supposedly active watery preparations, no evidence being given that the batch of material tested was active at the outset. But among the results of assays presented with admirable candour by Dr. Frank there is no example of a preparation found to be highly potent which showed rapid subsequent deterioration. The author's comment upon the Aschheim-Zondek test for pregnancy—that the

test is unworkable since the immature mice die long before the completion of the test—has been disproved by several investigations during the past year. Such statements detract from the value of the book, which is to be regretted, since Dr. Frank's experience permits him to present an interesting case for the use of his own test for the diagnosis of pregnancy and for certain ovarian disorders, based upon the estimation of the amount of oestrus-producing hormone in the patient's blood. This section occupies about 120 pages compared with 149 pages dealing with biology, pharmacology, and chemistry. In his foreword the author comments on "this much desired and sought for hormone, which is bound to relieve many of the ills from which women now suffer." Is it really certain that administration of the oestrus-producing hormone will have this result on human patients? Clinical investigations have as yet been relatively few, and though encouraging results have been reported with admittedly active preparations, it seems doubtful whether they justify such optimism.

RHEUMATISM.

A Study of its Nature and Cure. By CHARLES E. SUNDELL, M.D., M.R.C.P. Lond., Senior Physician to the Seamen's Hospital, Greenwich; Consulting Physician to the Evelina Hospital for Children. London: Southern Libraries, Ltd. Pp. 88. 4s. 6d.

THERE is little that is new, but much that is useful in this little book; it has the merit of being short and easy to read. Several paragraphs are devoted to the diagnosis and treatment of chronic backache, a common and depressing complaint which at present does not receive sufficient attention. In the early part of the work the author defines what he considers to be the fundamental abnormalities in rheumatism and these defects he attacks logically and thoroughly in the section on treatment.

COLPORRHAPHY AND RHEUMATISM.

Recent Work on Colporrhaphy, Rheumatism, and Coli Bacilluria. Second edition. By E. HESKETH ROBERTS, F.R.C.S. Edin., M.D., B.S. Lond., Gynecological Surgeon, St. John's Hospital, Lewisham. London: H. K. Lewis and Co., Ltd. 1930. Pp. 32. 3s. 6d.

THE first part of this little book deals with recent work on colporrhaphy, and will be of real value to those who perform this operation. The method of procedure is discussed in detail and is clearly illustrated by numerous diagrams. The second part of the book is concerned with rheumatism and its relation to the perineal conditions for which colporrhaphy is performed, and coliform bacilluria. This section is too indefinite to be useful; an ill-defined disease is blamed for a vague collection of symptoms. Contrary to the author's belief, coliform bacilluria is a recognised source of infection in chronic rheumatism.

X RAY INTERPRETATION.

Elements d'interprétation radioscopique et radiographique des poumons. By Dr. LÉON SCHEKTER (de Boulogne-sur-Mer). Paris: Gaston Doin et Cie. 1930. Pp. 94. Fr. 12.

IN this little book Dr. Schekter gives a brief description of X ray shadows produced by the different diseases of the lungs. It is now recognised that considerable disease and even a large tumour may exist in the lung without any physical signs, though the lesion is quite obvious on X ray examination. The interpretation of X ray shadows is, however, a matter of great difficulty, and it is not uncommon to find a patient condemned as consumptive because of shadows which are within normal limits. It is, therefore, as dangerous to over-rate as to underrate the value of X ray examination.

This volume will be found useful by the practitioner who has not the time to study the larger text-books on the subject, for though the descriptions of the various conditions are very brief, there are many references to authorities where more detail can be found on any special point.

THE LANCET.

LONDON: SATURDAY, MAY 10, 1930.

PRESENT-DAY EFFECTS OF WAR STRAIN.

COMPLAINT is made by the writer of a letter in the *Daily News* that, when what he calls some wretched derelict of the war is brought before a judge and pleads a war wound or strain of war as an excuse for his trouble, a common judicial retort is that the war is a long way off and such excuses no longer serve. Such incidents do occasionally occur, and illustrate the need, referred to in a recent leading article, of the psychological examination of offenders, for at present the only course open to a magistrate who takes the plea seriously appears to be that of remanding the prisoner to await a report from the prison doctor. Those engaged in the treatment of war neurosthenics often meet with men who, after having fallen into the hands of the police, expressed gratitude for the way they had been understood and handled, and it is gratifying to know that both police and prison officials are ready to give help when they recognise that help is needed; but the cases under discussion indicate the absence of regular machinery to ensure that recognition, and the summary dismissal of the defendant's plea may not only involve injustice but seriously and detrimentally affect a genuine sufferer, whilst even the prison doctor to whom he might be referred may not possess the knowledge of psycho-pathology necessary for the understanding of his mental state.

Setting aside for the time, however, the problem of psychological assistance in court procedure, we may ask whether the mental results of war stress are now a closed book or whether any considerable number of men are still suffering from them. There are still thousands of men drawing pensions for these results, and the Ministry of Pensions maintains homes where the worst cases can find a refuge, but apart from these recognised cases it is impossible to do more than guess at the prevalence and effect of disability due to war stress. Of its victims the more fortunate have overcome their difficulties and found satisfaction in life, others are holding inferior positions through inefficiency, and some have become hopeless derelicts. Employers soon became chary of employing men who had been invalided for neurosthenia, and their attitude is understandable when we realise that under that vague diagnosis are hidden changes in the personality that render the sufferer emotionally unstable and unreliable as a worker. Public attention and sympathy are no longer directed towards the neurosthenic ex-Service man, and it is to be feared that he often meets the fate that comes upon victims of a disorder likely to be described as neurotic and offering no opportunity to ordinary therapy.

Reports of suicides often mention changes of behaviour attributed to war service, though definite medical evidence is rarely sought—perhaps because such changes are still felt to be outside the sphere of clinical medicine; and only by reading between the lines is it sometimes possible to form an opinion as to the nature of the case. Those who pay special attention to the psychoneuroses certainly still meet with patients whose symptoms are related to war experience, and it has been claimed that it is possible

to demonstrate the process of suppression, characteristic of the war cases, as still active in ex-Service men who present nervous symptoms, whether supposed or not to be due to war strain. There is, then, no doubt that the nervous sufferer from the late war is still with us. The fading away of emotional public interest in his troubles is not entirely to be regretted, for deteriorative character changes often led a man to take advantage of the emotional appeal rather than coöperate in efforts at rehabilitation. He who complained least often suffered most, for, in spite of a common belief to the contrary, the patient suffering from mental troubles, such as marked many of the war cases, tends to keep them to himself. It is to be hoped that emotional interest will not be replaced by the neglect that in the past was associated with ignorance of psycho-pathology; indeed, there is less danger of that neglect for the very reason that the war itself gave a great stimulus to the study of the minor psychoses. We know now that the war cases differed only superficially from cases, equally serious, that occur in civil life; apart from the help given him by the Ministry of Pensions, the war sufferer must stand or fall with his fellows who have never had the right to claim that help. The plea of war strain in our courts thus becomes only a special example of the need for an organised method by which all relevant information about an offender should be placed at the service of those called upon to pronounce judgment upon him.

END OF THE POOR-LAW IN SCOTLAND.

ON Thursday next Scotland's particular Local Government Act comes into force and the poor-law functions of parish councils pass over to the town councils of the large burghs. The zeal and care with which the parish councils have discharged the duties of their last year in office is commended in the first report which has been put out by the new Scottish Department of Health.¹ One of their chief problems of late years has been the relief of able-bodied unemployed, which still calls for anxious consideration of individual cases. In 1921 parish councils were empowered to grant relief to able-bodied persons who were unable to find employment. This was intended as a temporary measure, but the difficulties which have arisen out of it make the remedy almost as unsatisfactory as the problem. Later Acts which empowered the councils to coöperate with other local authorities in providing relief work for these men, or to assist them to emigrate with their families, can only be of value in a few cases while the number of able-bodied unemployed remains so large. Unconditional financial relief, although tending to preserve the standard of health, may lead to a habit of idleness which is injurious alike to the man's physique and his morale. The refusal of all relief except residence in a poor-law institution is not a satisfactory measure, since if relief is accepted the man is no longer in a position to seek work, and if he is genuinely unable to find employment refusal to accept indoor relief will leave him destitute. If relief is refused to a man because of prolonged unemployment, but granted to his family, the result is that he shares, as a rule, in relief which was not intended to suffice for a whole household. Again, a man who has made serious attempts to find work resents being forced to share institutional life with those who have been refused outdoor relief on the grounds of bad character. In Glasgow during the past year employment

¹ First Annual Report (1929) of the Department of Health for Scotland. Cmd. 3529. H.M. Stat. Office. 1930. Pp. 220. 3s. 6d

was found for a large number of men on a new mental defective institution, the alimient which they would otherwise have received as outdoor relief being contributed to the District Board of Control which was erecting the building. Men unemployable in the present state of the labour market, either through mental or physical defect or through depraved habits, represent an even more serious difficulty. It is customary to offer only indoor relief to these cases, but their presence in the institution is a source of discomfort to the other inmates, and certainly does not simplify administration. It has been suggested that labour colonies are required for the reform or training of such persons.

Unemployment in Scotland remains high and has increased since 1928; during 1929 the average number of unemployed represented 12·3 per cent. of the insured population. In 1927 and 1928 the corresponding figures were 10·1 and 11·6 per cent. respectively, and there has been a real as well as a relative increase in the numbers. In the coal-mining industry there was improvement as compared with 1928, but in shipbuilding unemployment remained high; in marine engineering unemployment was below the general average. Certain industrial areas show marked improvement, Clydebank, Greenock, and Port Glasgow being among them. Vagrancy has increased of late years owing to movement about the country of men in search of work. Applications for relief are made to inspectors more especially along the main roads, so that the burden on parish rates is unequally distributed. Often there is no poor-law institution for 30 miles or more, and construction of shelter houses may become necessary. Unfortunately a taste for tramping appears to grow on those who pursue it indefinitely; many able-bodied young men appear to prefer the life of a tramp, picking up occasional odd jobs, to the monotony of steady employment. GEORGE BORROW and W. H. DAVIES in their defences of vagrancy might have spared more sympathy for the mournful lot of the ratepayer, who, besides drudging through the daily round, must maintain the road which the tramp wears out, and if necessary must subsidise the tramp as well. Not uncommonly, in a Scottish parish where an arrangement is made by the council with a householder for sheltering and feeding vagrants, the tramp will ask for another egg and offer to pay for it himself. One of the tasks of the new authorities will be the provision of better institutional accommodation. At present it is not uncommon in Scotland to find acutely sick persons, chronic invalids, senile poor, young children, able-bodied poor, vagrants, mental defectives, and lunatics all in the same institution; the disadvantages of such a system, especially for young children, cannot be too strongly emphasised. The imminence of local government reform has deterred parish councils from undertaking extensive building during the past few years, but the new régime will call for the provision of more satisfactory accommodation.

CALCIUM AND PHOSPHORUS.

KNOWLEDGE of the part played by calcium and phosphorus in the metabolism of the human body has greatly increased during the last ten years and the practical value of this knowledge is beginning to be recognised. But most medical men still have but a dim appreciation of what has been ascertained, while a few have been able to grasp its value in one direction or another. Where new territories are being explored and defined, it is difficult for those who are not

engaged in the work, difficult even for those engaged in it, to see its significance and to estimate its value to mankind. Our readers, therefore, will welcome the full and careful review in Dr. DONALD HUNTER's Goulstonian lectures, of which the third and last appears in THE LANCET this week, and especially the indications he has given of the practical value to clinical medicine of the recently acquired knowledge. On the metabolic processes that concern calcium and phosphorus depend the efficient formation of the bony structures of the skeleton, and that balance of the ions in the body which controls the acid-base reaction of tissues and fluids, the mechanism of the heart-beat, the contractility of plain and striped muscle, the activity of neuromuscular junctions and synapses, and the irritability of muscle and nerve. That the metabolic processes that concern calcium and phosphorus should be correctly performed depends on the ingestion of these elements in sufficient quantities, on their absorption by the digestive processes, on their storage in the skeleton so that they may be readily available when required, and on their presence in the tissues and body fluids in the necessary concentrations and in the necessary physical forms so that they may be available for the biological needs of the tissues and organs. These manifold requirements and functions depend, also, on the integrity of a mechanism in which an accessory food factor, vitamin D, the internal secretion of the parathyroid glands, and an enzyme called phosphatase, play their parts. Phosphorus functions in the storage and utilisation of carbohydrates, and since calcium is stored in the bones as calcium phosphate and phosphorus must be set free with calcium when the stores of the latter are drawn upon, phosphorus metabolism is as important as that of calcium, and the one cannot well be considered apart from the other. It is a long chain of cause and effect. Studies of this nature, whether in human beings or in experimental animals, are necessarily complicated and difficult. Much information is obtained by ascertaining the amount of calcium and of phosphorus in the blood, but in view of the enormous capacity of the skeleton for storage such estimations are indicative merely of the quantity of these elements available for the tissues generally; estimations of their intake and output over a considerable number of days are needed before the loss or gain to the body as a whole can be deduced. Part only of the calcium in the blood is diffusible and able to pass into the tissues and tissue fluids, and of this diffusible calcium a part only is ionised and available immediately for biological processes. The methods for the estimation of these different fractions are not yet satisfactory, and the estimation of the total calcium of the serum, which is the method of study in general use, does not necessarily give the facts that are required. Improved methods of blood analysis may be expected to lead to important further advances. Dr. HUNTER shows clearly that histological study of the bones is required in addition to biochemical study before the disturbances of calcium and phosphorus metabolism that occur in disease can be accurately gauged. He has had the help of Prof. H. M. TURNBULL in the minute examination of bony structures, and their results are good evidence of the productiveness of such coöperation.

Of the applications to clinical medicine none is so dramatic as the recognition of the effect of hyperactivity of the parathyroid glands on the skeleton. The isolation from the parathyroid glands by J. B. COLLIP of a substance that produces on injection a rise of calcium in the serum with increased excretion by the kidney, and the recognition by HUNTER and AUB

that injections of this parathyroid extract cause a loss of calcium from the bones, are important steps in deciding that in certain cases of generalised osteitis fibrosa the diminished density of the bones, the high calcium content of the serum, and the increased calcium excretion point with certainty to a lesion of the parathyroid glands. A number of cases have been recorded in which an incision in the neck has revealed a parathyroid tumour, after removal of which the patient at once improved, the calcium content of the serum fell, and the bones became more dense. In exophthalmic goitre the density of bone is diminished and the excretion of calcium greatly increased, but in these cases the level of calcium in the blood does not rise—why we do not yet know. Prof. TURNBULL's observations on the histology of the long bones make it clear that both in exophthalmic goitre and in hyperactivity of the parathyroid the diminished density of the bone is due to lacunar resorption by osteoclasts and is quite distinct from the diminished density seen in rickets and osteomalacia in which less calcium is laid down in the osteoid tissue. In striking contrast to the condition of hyper-parathyroidism is that seen when the parathyroid glands have been partially removed or damaged during the operation of thyroidectomy. Tetany may then result, associated with low calcium and high phosphorus contents of the blood, and can be relieved by the injection of Collip's parathyroid extract. Tetany may also occur in osteomalacia and some cases of rickets, where the calcium content of the serum is low; but in these conditions it is not advisable to inject parathyroid extract, for this would cause withdrawal of calcium from the bones, which are already poor in calcium salts. Instead the underlying disturbance must be treated, when the calcium content of the serum will rise and the tetany will be relieved. In rickets and osteomalacia the changes in the minute structure of the bones have long been known to be similar, but it is only recently that many workers in many lands have contributed to show that in both the changes are due to the same cause—namely, a deficiency of vitamin D—and that the ingestion of irradiated ergosterol or exposure to sunlight can cure both conditions. In both the phosphorus content of the plasma is low; in osteomalacia the calcium content of the serum is also low and tetany is common; but in rickets the calcium content may be normal and tetany is not common, being only seen in those cases in which the calcium content also is low. In renal rickets the phosphorus content of the plasma is raised and the calcium content lowered, probably as a secondary result of the high phosphorus content, and tetany is frequent.

Estimations of the calcium and phosphorus content of the blood have, therefore, considerable value in diagnosis, and Dr. HUNTER has included in his third lecture a valuable table showing the results of his estimations in typical cases. He discusses other diseases of bone, and indicates how estimations of the phosphatase content of the plasma may lead to important advances. Little is known of the aetiology of osteitis deformans, but H. D. KAY has shown that phosphatase is always in excess in the plasma in this disease. AUB, HUNTER, and others have shown that lead, mercury, arsenic, silver, and radium follow calcium very closely in their behaviour, both as to storage in the bones and elimination. This experience has already been applied in the treatment of lead poisoning and should help us to understand the mechanism of metallic poisoning in general and how to deal with it. Stiff-sickness of cattle is associated with abnormal development of the skeleton, and the investigations of THEILER have shown it to be an osteomalacia of the

low-phosphorus type, curable by the addition of phosphates to the diet; similarly, milk-fever of cows is associated with a low calcium content of the serum and can be successfully treated by calcium injections. Accuracy of knowledge leads surely to success in treatment, and Dr. HUNTER's comments on the disappointing results of the administration of calcium in disease deserve the attention of clinicians. The stores of calcium in the body are large and it is usually, he says, the regulating mechanism that is at fault, not the supply. From this it follows that the use of cod-liver oil, ultra-violet light, irradiated ergosterol, parathyroid and thyroid extract may have greater value than the administration of calcium. These are but examples of the way in which our increasing knowledge of calcium and phosphorus metabolism may be applied in human and veterinary medicine, curative and preventive. They illustrate well the progress which is made when the clinician invokes the aid of biochemistry and of pathology and applies their methods to the solution of his problems.

Annotations.

"No quid plura."

WELFARE OF THE BLIND.

THE eighth report of the Advisory Committee on the Welfare of the Blind¹ follows on the lines of its predecessors. According to the latest returns there are 20,149 registered blind persons between the ages of 50 and 70 in England and Wales, and 86 per cent. of these are in receipt of pensions provided for in the Blind Persons Act of 1920 at a cost of £437,000 per annum. The committee thinks the reduction of the age limit from 50 to 40 would be fully justified, but they do not consider how this suggestion, if carried out, would affect those of the blind who have been trained for remunerative employment at an earlier age. Schemes for promoting the welfare of the blind have now been adopted and put into operation by all the 146 local authorities concerned under the Act of 1920, at a cost of £320,709 (1928-29), about one-third of this sum being allocated to assistance to unemployable blind on whom between two and three times as much was spent as was the case two years before. Most of this money has been distributed through voluntary agencies, who have also received direct grants from the Ministry of Health to the extent of £120,000 (1928-29). With regard to the future, the Local Government Act of 1929 changes the system of Government grants, but the committee sees no reason to fear that the amount available for assistance to the blind will be less than heretofore. Indeed, it is hoped that the Act, as finally passed, will considerably strengthen the position of voluntary agencies.

The total number of the registered blind in England and Wales in 1929 was 52,727. Infantile blindness accounts for only a small proportion of this total. The number of registered blind under the age of 5 was 258, or 0.5 per cent. of the total of all ages. We suggest that this figure is wholly unreliable as representing the actual proportion of infantile blindness, and that the vast majority of blind infants are not registered as blind until they become inmates of a blind school after the age of 5. The main causes of infantile blindness are ophthalmia neonatorum, congenital syphilis, and various congenital conditions, including congenital cataract. In an examination of 250 pupils and workers at the Swiss Cottage Blind School in 1927 it was found that out of 180 who had a degree of blindness coming under the definition accepted by the Ministry of Health, as many as 102

owed their blindness either to ophthalmia neonatorum or to congenital malformations, including cataract, all of whom must have been blind within the first six months of life.² That over a third of the cases of blindness dating from infancy in the whole of England and Wales should be collected at a single institution in London, which is by no means unique, is not at all likely, and we should like to be told exactly how the registration of the blind is effected. It may be added that previous reports of the same committee in 1926 and 1928 have contained similar figures of the proportion of the blind under 5 years old, and in criticising both these reports we had to make exactly the same complaint. The 1928 report also contained figures showing that the percentage of the blind who became blind under the age of 1 year compared to the total number of blind was 17·4 in the year 1927—a fact which is itself a sufficient refutation of the percentage of 0·5 for the proportion of blind existing at that age; for although the proportion of blind from ophthalmia neonatorum has been decreasing to some extent of late years the decrease has not been phenomenal to such an extent.

We regret to observe that in this report there is no reference to the partially blind children who, being too blind to benefit by education in ordinary schools and yet not blind enough to qualify for the special privileges conferred on those termed blind by a somewhat arbitrary standard, are at present apt to fall between two stools. In 1926 the committee expressed the hope that "it would be possible for the Board of Education to proceed with their full programme for the development of extended facilities for the education of this class." In 1928 the report commends the same problem to voluntary enterprise, but as yet we know of no progress in either direction.

In the past the reports of the committee have been largely devoted to the methods of training the blind in remunerative employment. The present one lays stress on the more numerous class of unemployables, in whose interest they have issued a special report to the Minister containing recommendations for financial and general betterment.

RESEARCH INTO BREWING.

For many centuries malting and brewing were empirical arts, but in later years these industries, in common with others of long standing, have adopted scientific principles for the methods underlying their practice. The nature of certain investigations carried out by the Institute of Brewing, and still in progress, is described in a memorandum recently issued by the Institute, and from this document it is evident that the various researches are of considerable magnitude, and well meriting the free assistance that is being given to their conduct by members of agricultural institutes and by industrial firms in this country and elsewhere. The work includes the development of new varieties of barley, the investigation of different agricultural conditions such as manuring, the breeding, manuring, drying and packing of hops, methods for overcoming the attack of "downy mildew," and the determination of anti-septic value. In connexion with yeast the work has been mainly directed to the assimilation of various nitrogenous materials by this fungus, whilst experiments on its nutrition are still in progress. Many interesting and valuable results have already been obtained, and whilst the knowledge gained will be of value to the brewing industry the inquiries are of such a fundamental nature that they cannot fail to be of service to the community at large. Pharmacology may also profit, for barley and yeast are the raw materials from which valuable medicaments such as malt extract and nucleic acid are derived. Moreover, the use of hops was a prominent feature in old pharmacopœias.

MEDICAL ANNUALS.

THE *Medical Annual*¹ suffered the loss of its founder and first editor, Dr. Percy Roberts Wilde, in April of last year. The success of his scheme to help the general practitioner to keep up to date must have gratified Dr. Wilde, for since he initiated the first issue in 1882 the annual has grown at first in size and then in prestige until it has become almost indispensable. In 1905 its format was altered, and since then it has not been allowed to expand. The task of editing a summary of current medical advances entails nice judgment and great labour, and though of late years Dr. Wilde had relinquished much of the responsibility, he continued until his death to take a share in the preparation of the *Medical Annual*. The 1930 volume contains articles by recognised authorities on the research and practical experiment of the year, and the editors, Dr. Carey F. Coombs and Mr. A. Rendle Short, review the contents in their introduction. An article by Dr. Ivor J. Davies on the liver treatment of pernicious anaemia deals at length with prognosis, which can, of course, be estimated better as the years pass. One of the secondary effects of the treatment is a rise in the price of raw liver, so that patients find difficulty in obtaining a steady supply. This depends partly on the promiscuous liver treatment of all manner of ailments, a craze which requires correction if cases of pernicious anaemia are to enjoy the benefit of this diet. The value of other foods in this disease, such as kidneys, apricots, and peaches are mentioned, but it is emphasised that these, like liver, only stimulate the development of red cells and have no effect on the underlying pathological process, whatever it may be. The clinical experiments devised by Dr. W. B. Castle to elucidate this process are mentioned in this excellent survey. The intramuscular injection of liver extract as a treatment of high blood pressure is discussed in an article by Dr. A. G. Gibson; the method has been examined by Althausen, Kerr, and Burnett, and appears to cause a temporary fall in pressure, without, it is claimed, any adverse effects. The rationale of the treatment is not discussed. An interesting but depressing section is that on pain in the lower part of the back by Prof. E. W. Hey Groves. After shattering the old theory of pelvic disease, grudgingly conceding arthritis, doubting the existence of sacro-iliac dislocation apart from severe trauma, and moodily holding the scales for strain of the sacro-iliac joint as a cause, Prof. Hey Groves confirms the obscurity of the outlook by a warning against acceptance of anatomical deformity, radiographically discovered, as the basis of any symptom-complex. There is a helpful paragraph on the differential diagnosis of sacro-iliac and lumbo-sacral strains and sprains, especially useful in view of Mr. Riches's experience that the former alone react favourably to manipulation,² and a short reference to the work of C. E. Ayers on lumbo-sacral backache due to compression of the fifth lumbar nerve. The paragraph on the treatment of these conditions is brief and pessimistic; the article is well illustrated with X ray plates and a diagram of the fifth lumbar root. A section on the treatment of burns and scalds, by Sir William I. Wheeler, gives an excellent description of the tannic acid method, which is now extensively used for severe burns. Application by means of an atomiser is recommended. It will be remembered that spraying is repeated until a leathery coagulum is formed which protects the injured surface and prevents toxic absorption; the coagulum begins to separate after about a fortnight, and leaves either a healed epidermis or a healthy granulating surface. Sepsis occurring beneath the coagulum sometimes gives rise to trouble, and may require the removal of a part with scissors to allow of the escape of pus. A warning is given against the use of vaseline or moist

dressings to remove the coagulum, lest the toxin previously imprisoned should be released by solution. The annual is arranged alphabetically and is excellently illustrated; the decision to keep it to a size convenient to handle has had the further advantage of ensuring a careful selection of material and its limitation to what is of practical interest.

L'Année Médicale Pratique,¹ which attempts to fulfil the same functions in France, is a more modest volume, and the absence of illustrations other than the most diagrammatic make it less attractive. It also provides a survey of the year's work by various authorities. The sections are on the whole briefer, and view the subjects from a different angle. For example, liver treatment of anaemia associated with nephritis is discussed; the view is put forward by C. Lian that the anaemia is much improved in these cases by liver, and that the nitrogen retention, far from being augmented, is decreased. In a case described by Marcel Labbé, however, though the blood count was increased, the blood-urea also continued to rise. The articles are perhaps too brief to give a comprehensive survey of the year's advances; the editors might consider enlargement of the volume as a possibility in the future. Both the English and French annual include a list of preparations, chiefly proprietary, which have come into use during the past year, with a short description of their composition and advantages.

IMMUNISATION AGAINST FILTRABLE VIRUSES.

MUCH attention is now being paid to prophylactic immunisation against those disease agents which we group together under the term "filtrable viruses." Not very long ago it was accepted almost as axiomatic that no immunity could be obtained against these viruses without the production of lesions, but recent research has shown that this is not true. The independent observations of Vallée, Carré, and Rinjard in France, and of the British Foot and Mouth Committee, show that if the virus of foot-and-mouth disease is inactivated with low concentrations of formalin it still retains the power of conferring immunity, whereas its antigenic power is entirely lost on inactivation by heat. This principle has since been applied to other viruses—among them those of distemper and yellow fever—and prophylaxis against distemper along these lines has been practised in the field with success. Whether the formalised vaccine is dead or merely attenuated is still in dispute, but whichever view be correct, it must be admitted that the immunity evoked by these vaccines is never as solid or as durable as that called out by live virus. Obviously the use of live vaccines has its dangers and limitations. In vaccination against small-pox advantage is taken of the fact that the virus of small-pox, when adapted to the cow, is altered in such a way that when implanted in human skin it gives rise merely to a local lesion, the evolution of which nevertheless confers immunity to small-pox. That this method of vaccination does not represent the ideal is shown only too clearly by the puzzling sequels reported during the last few years. Perhaps a stricter attention to dosage might mitigate or remove this disadvantage, but, be this as it may, the underlying principle involved is an important one, which must be kept in mind. In this respect recent work on the prophylaxis of fowl-pox is of interest. The viruses of fowl-pox and pigeon-pox are immunologically identical, but have so great a species adaptation that the possibility of using live vaccines of the latter virus for immunising fowls against fowl-pox suggested itself. In 1928 Lahaye² and Zwick, Seifried, and Schanck³ attempted this with some success, and Doyle⁴ has now studied the subject afresh. He finds

that pigeon-pox virus produces minimal lesions in the hen with no tendency to generalisation and no interference with health; furthermore, the virus does not spread from inoculated to normal birds even under conditions most favourable to contagion. The living vaccine is applied to a small area of skin denuded of feathers, and as a result of the mild infection which ensues the bird becomes immune to fowl-pox. This immunity is fully developed by the end of the second week and, although it does not confer complete protection against artificial infection, the immunity to natural infection is a solid one. Whether this method will prove superior to the use of heat-killed vaccines, which have their advocates, only extensive trial in the field will show, but Doyle reports that during the last six months over 50,000 doses of live vaccine have been supplied for use in infected flocks, and that the results have been very satisfactory.

NEONATAL DEATH.

Yandell Henderson has said that the first quarter of an hour after birth is the most dangerous period of life, and that nothing in medical practice so nearly resembles the methods of the dark ages as those employed in dealing with the new-born baby which does not breathe. Dr. J. N. Cruickshank's study of neonatal mortality (see p. 1032) goes far to confirm this dictum, and shows that the great majority of deaths during the first month actually take place during its first few days. Of 800 infants who failed to live a month he found that no less than 71 per cent. died within a week. The problem of infant mortality—meaning the death of infants who have really established independent existence—is no longer so serious as the problem of stillbirths, for the causes of stillbirth are the causes of very early death. The death-rate in the first week of life is given by the Registrar-General as 23.5 per thousand live births, and in the city of Glasgow the figure is about the same, while for the second week the Glasgow figure is only just over 5 per thousand.

By far the commonest cause of this wastage of infant life is asphyxia and atelectasis, which account for 546 of Dr. Cruickshank's 800 deaths. Theoretical considerations suggest that during its last few weeks in the uterus every foetus undergoes gradually increasing asphyxia corresponding with the gradual narrowing of the ductus arteriosus. The venosity of the blood reaching the foetal brain is further increased during labour, when the placental circulation is cut off, and finally the concentration of carbon dioxide becomes so great that the respiratory centre is stimulated to initiate lung breathing. Unfortunately, excess of carbon dioxide paralyses instead of stimulating the respiratory centre, and if the concentration becomes too high the child is born asphyxiated or else the centre fails to establish respiration fully and patches of lung remain unexpanded. At present we have no satisfactory methods of rescuing the respiratory centre from its embarrassment. If one of the contributory causes is hemorrhage, either from gross injury or from asphyxial ecchymoses, violent attempts at resuscitation may well make matters worse. Dr. Cruickshank suggests the remedy, well known to anaesthetists, of supplying oxygen with 5 per cent. of carbon dioxide, besides ensuring absolute rest, warmth, and quiet, and cleansing the respiratory passages from the amniotic fluid and meconium so often found in them. On the preventive side, improved antenatal supervision is bound to reduce the incidence of asphyxia, prematurity, and birth injuries. Miss Joyce Partridge, as a result of investigations⁵ made under her Riddell Research Fellowship at the Royal Free Hospital, concludes that nearly half the infants who are alive at the commencement of labour, and yet are born dead to healthy mothers, die solely because they have sustained intracranial injury at the time of birth. She regards relaxation of the pelvic

⁵ Jour. of Obstet. and Gyn. of the Brit. Empire, 1930, xxxvii., 18.

ligaments as a real aid to parturition, which may make all the difference to the clearance between the foetal skull and pelvic brim. In the pregnant woman an increase in the normal mobility of the joints can be recognised. In a series of 100 cases examined, there were four in whom joint movement was almost absent, and of these two had stillborn infants who suffered from intracranial injuries. In her view treatment based upon the presence or absence of antenatal mobility of the pelvic joints should reduce the numbers of stillbirths.

Another potent cause of early death is infection, either generalised or confined to the lung. It is difficult at present to say how this enters the body, but Dr. Cruickshank suspects the skin and respiratory tract, and finds no evidence for the widespread belief that the umbilicus and gastro-intestinal tract are common portals of entry. This group cannot be sharply distinguished from the first group, since prematurity is a common cause in both, and asphyxia and atelectasis predispose to the development of pneumonia. Dr. Cruickshank's investigations relegate both syphilis and congenital abnormality to a relatively unimportant place in the causation of neonatal death, except that the children of syphilitic mothers are often premature. Many so-called cases of congenital heart are really, he believes, cases of asphyxia livida.

The state of our knowledge hardly permits of very definite recommendations. Meanwhile all concerned with the improvement of maternity and infant life will agree with Dr. Cruickshank when he advocates better antenatal supervision, better education of doctors and midwives, more and better staffed hospital accommodation for lying-in women, and research into the problems of neonatal disease and prematurity. Ignorance of the actual cause of death has, he says, been one of the great obstacles to progress in the past. If a baby which is born blue and dies within a few days of birth is held to be suffering from some congenital cardiac abnormality, there is no stimulus to the obstetrician to worry about it. But neonatal deaths might be considerably reduced if every accoucheur came to feel that asphyxia after birth was as unnecessary and as curable as asphyxia under an anæsthetic.

A NEW CONCEPT OF TUBERCULOSIS.

At the Royal Society of Medicine (Section of Epidemiology and State Medicine) on April 25th Prof. S. Lyle Cummins discussed some of the clinical and pathological factors underlying mortality-rates in tuberculosis. It must be conceded, he said, that tuberculosis, in spite of the fact that its causative germ is known, and that it has been the subject of endless investigations, is still imperfectly understood. Its manifestations at different age-periods, and under different cultural and social conditions, vary as greatly as if not one but several diseases were concerned. Brownlee's analysis of death-rates in tuberculosis had suggested that behind tuberculosis mortality lay a complex and imperfectly understood disease. The epidemiologist, said Prof. Cummins, should bear constantly in mind: (1) factors concerned with infection, (2) those favouring or retarding the development of infection into disease, and (3) those leading on to or postponing the fatal termination. Each of these three sets of circumstances was, in its turn, dual in nature, depending both upon the infecting germ and upon the infected organism. Epidemiologists, therefore, should not passively receive and analyse the findings and records of clinicians and pathologists, but should actively associate themselves in the attempt to find new methods of approach. A first necessity seemed to him the formulation of some concept which would cover not only the known facts of the disease, but also the equally well recognised facts of infection without perceptible disease. His own observations had led him to such a formula:—

"The first stage of tuberculous infection is one in which the lesions are in a larval state, localised as a rule at or

near the portal of entry and in the nearest lymphatic glands, though as yet without any obviously harmful effect on the organism. This larval stage may lead on rapidly to the generalisation of the infection throughout the body, producing the natural tuberculosis characteristic of laboratory animals, infants and the adult members of hitherto uninfected communities after heavy infection; or it may remain latent in the form of larval lesions still capable, under disadvantageous conditions, of activation; or, if held in check, of creating the hypersensitive condition which leads to the inflammatory phenomena associated with reinfection and characteristic of the modified tuberculosis of later life in civilised communities. Alternatively, such larval lesions may serve only as a stimulus to the development of humoral and cellular resistance against the spread of tuberculosis, so that the infective process may end by becoming compensated and ceasing to be any further menace to health."

Such a concept, said Prof. Cummins, seemed to him to cover the known facts, and to afford a starting-point for further inquiries. The "larval" stage of tuberculosis could only be studied at autopsies, where death had occurred from other causes; and the contrast between "natural" and "modified" tuberculosis was also best appreciated in its pathological manifestations. "Modified" tuberculosis, of which the chronic phthisis of middle age was the most typical example, required study on clinical lines, and an examination of the survival periods of classified cases helped to throw light on this phase of the disease. The "compensated" tuberculosis of healthy adults represented a difficult problem which he had attempted to approach by means of tuberculin tests on quantitative lines.

RETIREMENT OF DR. A. B. RITCHIE.

ON April 23rd Dr. A. B. Ritchie retired after nearly twenty-seven years of service as medical officer to the Manchester Education Committee. The regular school medical service did not receive Parliamentary sanction until 1907, but Manchester was among the more progressive authorities which appointed its own officer before that time arrived. For six years Dr. Ritchie worked with one assistant, and in 1909 four medical officers and five nurses were appointed to assist him in carrying out the national scheme. His staff continually grew until at the present time it includes 19 full-time assistant medical officers, 4 specialists, 8 full-time dentists, 62 nurses, and 4 masseuses, while there are 9 school clinics covering the whole field of minor ailments and dealing with defective vision, the X ray treatment of ringworm and other skin affections, the ionisation of ears and the ultra-violet radiation of a variety of conditions. Dr. Ritchie also had medical charge of an epileptic school which accepts cases from all parts of the country and is the only one of its kind managed by an education authority. An orthopædic clinic is also now in operation, with two specialist surgeons; part of this scheme was the school for crippled children at Swinton, of which Dr. Ritchie had medical charge, and there is also a day cripple school, further developments being in contemplation. The ascertainment of mental deficiency has been under his control and the allocation of cases to the special schools. Of all this work Dr. Ritchie laid the foundations and built up a large part of the superstructure. On his retirement the medical and administrative officers both made him a presentation, and he received a token of appreciation from the teachers of the special schools for physically and mentally defective children. The gifts were tangible evidence of the real affection which Dr. Ritchie has inspired among his staff who although officially under his control were made to feel like professional colleagues; his reports always gave full credit for any special work done by his assistants. Dr. Ritchie's position of direct responsibility to the education committee is now unusual; the arrangement still exists at Birmingham, Leeds, Newcastle-on-Tyne, Stoke-on-Trent, and a few other places. The question of the relation of the public health department to the school medical

service will naturally arise on Dr. Ritchie's retirement, but it is evident that in an area of the size of Manchester the hands of the medical officer of health are already full with the work of the public health and poor-law services so that his control of school medical work can be little more than nominal.

ACADEMIC MEDICAL WORK.

THOUGH the origin of many of the British medical schools is independent of the universities, they have now all become attached to academic institutions while retaining a considerable measure of autonomy. They stand only on the fringe of academic life, however, for they are bound to regard with respect the prejudices of the voluntary hospitals which supply their clinical material, and to adjust the demands made by charitable institutions and by university conditions on the men who are chosen by a joint committee to serve both. The overwhelming amount of administrative work which falls to university professors, especially those attached also to hospitals, was the subject of comment in the last annual report of the Medical Research Council, and is emphasised by the report for the year 1928-29 of the University Grants Committee.¹ This committee notes that the embarrassment of excessive administrative work is not a new one; it was deplored over 40 years ago by the late Prof. Henry Sidgwick, of Cambridge, who made the following despairing entry in his journal: "Alas! with boards general and special, committees of boards, syndicates and sub-syndicates, there is a luxuriant fungoid growth of administrative work feeding on the best juices of academic life. One longs for a benevolent despot, 'one still strong man,' in a blatant University." The head of a big scientific department at a modern university, asked to estimate the proportion of his time spent on routine and administrative work, on teaching and on research, complains that research has usually to fight a losing battle against matters of urgency. He adds that men invited to join the department have given as a reason for their refusal the fear that administrative duties would prohibit their getting on with their own work, and that they are right.

The heads of departments, who are largely chosen in the first place for their original work, should assuredly be free to carry it out. The problem is partly, but not entirely, an economic one. The provision of secretarial assistance for heads of big departments would undoubtedly save a good deal of time, but even more, it seems, would be saved by such a simplification or rearrangement of a university's—and a hospital's—business as would lighten the labour of attendance at conferences and committees.

Other questions discussed in the University Grants Committee report deal with salaries, superannuation, tenure of office and status, the social life and employment of students, and the promotion of post-graduate scholarships. The report is partly statistical. It gives the detailed income and expenditure of some 60 universities or colleges subsidised by the Treasury through this committee, whose annual budget of £1,550,000 is to be raised next year to £1,800,000. Other tables show the number, age, and sex of the students, the faculties in which they are distributed, and whether the object of their study is to obtain a diploma, a degree, or a higher qualification. The overlapping of certain figures and the omission of all information about Guy's Hospital Medical School, which does not accept official help, necessitates scrupulous care before general conclusions are drawn from the tables lest inferences should not be justified. For example, in certain of the London medical schools the proportion of students who have acquired a diploma rather than a degree is apparently as high as 12 to 1, and in one of the schools 22 diplomas but no degrees were obtained in the year under review;

but since the degrees in medicine and surgery granted by the universities of Oxford and Cambridge are included only in the figures of these universities, this proportion of students in each school reading for the diploma of the conjoint or any other board, and not for a university degree, cannot be ascertained. The omission of Guy's indeed diminishes the value of all the comparative information provided about the London schools, but a good deal may be inferred from the figures given. The examination of the tables included in succeeding annual reports of the University Grants Committee gives a fair moving picture of the waves of popularity of the institutions composing the universities of the United Kingdom.

INJECTION TREATMENT OF PILES.

SLOUGHING occasionally occurs after injection of hemorrhoids with 5 per cent. quinine-urea, and Dr. B. Saad, of Beirut, reports an incidence of ten such cases among 600 injections. The usual symptoms, he says, are immediate pain of variable extent, a feeling of weight in the rectum, dysuria, and a constant desire to defecate. A swelling can be palpated with the finger, and proctoscopy shows a sloughing pile. The slough takes 10 to 15 days to separate, and always heals. There are several causes of this complication, the commonest being reinjection of a pile already sclerosed by a previous injection, or too superficial injection. Saad repeats Bensaude's advice—never to inject an external pile or a prolapsed internal pile without first reducing it, and never to inject a pile that is already sclerosed. Furthermore, the injection should always be made deep into the submucous layer. For treatment of a slough, hot baths and local application of Ziehl's solution are recommended.

ETHYLENE ANÆSTHESIA.

THE acceptance of ethylene as an anæsthetic has been far wider in the United States and in Canada than in Great Britain. A questionnaire recently circulated to hospitals in America elicited replies relating to 332,721 administrations of the gas. This popularity may perhaps follow naturally the fact that the modern use of ethylene was initiated in Chicago. The gas had been tried as long ago as the middle of last century by Dr. Thomas Nunnely, of Leeds, but it had never come into general use at all, partly, no doubt, through chemical difficulties in preparation. The reason why it is not very frequently used in England appears to be mainly that its advantages over nitrous oxide are so slight when the latter is given in the manner now made possible by the evolution of efficient and easily controlled machines. Ethylene is a little the more potent of the two gases, and has superior relaxing powers. This slight advantage, however, hardly seems to weigh against nitrous oxide used with judicious addition of small amounts of ether. That, at any rate, was the conclusion we arrived at after listening to the discussion which followed Mr. R. J. Clausen's paper at the Royal Society of Medicine and to that excellent paper itself. Mr. Clausen was an enthusiastic but judicious advocate of ethylene after the experience of 371 cases. He had administered the gas for as long as 2 hours and 25 minutes in one case. The main objection to ethylene in the minds of many is its highly offensive smell. Mr. Clausen meets this by conducting away the patients' expirations through a length of rubber tubing which terminates either at the edge of the theatre or actually outside it. Apparently about 60 gallons of the gas are needed per hour, and in abdominal cases it is almost always necessary to use some ether to obtain due relaxation. The risk of explosion does not appear to be so formidable a bogey here as in America. The questionnaire referred to above revealed ten instances of explosion, involving three minor injuries, four destructions of equipment, and one death.

CONTINUOUS BATH TREATMENT OF HEBRA.

TREATMENT by continuous immersion is associated with the name of Ferdinand Hebra, who employed it for various kinds of cutaneous diseases half a century ago at the Allgemeines Krankenhaus in Vienna. In the *Journal of the American Medical Association* for April 5th Dr. Gustav Riehl describes the present day applications of Hebra's method. The construction of the bath is designed to permit of the immersion of patients for periods of days, weeks, or even months continuously in plain water, medicated if necessary, at a temperature ranging from 85° F. upwards according to the requirements of the individual case. Mechanical arrangements ensure the easy transference of the patient into and out of the bath, the maintenance of a uniform temperature, and the rapid cleansing of the bath. At the hospital there are 22 of these baths in operation. Good results are claimed in the treatment of extensive burns, psoriasis, acute generalised dermatitis, weeping eczema, pemphigus, erysipelas, and other affections of the skin; of surgical cases, including septic wounds, discharging sinuses, fistulae, bed-sores, and frostbite; of medical cases such as painful polyarthritis; and among neurological cases of myelitis, multiple sclerosis, tabes, tetanus, and certain psychical disorders accompanied by agitation or delirium. In this country such treatment has never been extensively employed. Years ago it was advocated by Sir James Barr in the treatment of typhoid fever, but the method never came into general use. Prolonged immersion, of some hours' duration, is employed on occasion in the treatment of skin affections and, for its sedative effect, in psychological disturbances; but there is no installation comparable to that described by Dr. Riehl, treatment when given being in some simple adaptation of the ordinary bath at home or in hospital. The continuous bath involves the use of expensive apparatus, special nursing and attendance, and is only practicable in an institution. In view of the wide range of cases for which benefit is claimed, such an installation should be attached to a general hospital, but the expense of installing, maintaining, and operating a suite of such baths would hardly be undertaken by the management of any hospital unless convincing evidence is brought forward that continuous immersion offers advantages in a wide range of maladies, unattainable by simpler methods. In the case of extensive bed-sores, burns, and septic wounds, the Viennese experience is certainly such as to render the method worthy of imitation in this country; a beginning might be made with a few experimental baths, to be extended if found to justify their existence. Possibly one or other of the new clinics for the treatment of rheumatic disorders might offer facilities for a trial.

VETERINARY RESEARCH IN SOUTH AFRICA.

THE first report¹ from the Onderstepoort Laboratories under the new director, Dr. P. J. du Toit, successor to Sir Arnold Theiler, lacks none of the excellence of previous reports, and there is substantial gain from the grouping of the articles into nine sections: protozoal diseases, virus diseases, bacterial diseases, parasitology, pathology, diseases due to poisonous plants, sterility, mineral deficiency, and miscellaneous. No one can study it without being impressed with the value, not only to the agricultural community but to the country generally, of State-aided research in veterinary science. The money expended by the Union of South Africa upon the development of the splendid organisation at Pretoria and upon its maintenance must have been repaid many times over by the results achieved in the prevention of animal diseases. Practical recog-

nition of the value of the work to the Empire has now been given by the award of a capital grant of £10,000 and an annual grant of £11,000 for five years from Empire Marketing Board funds. A series of excellent photographs in the report shows the laboratory buildings and the animal accommodation. The laboratories have an extensive staff, the professional members of which alone number nearly 30.

One or two points of special interest may be selected for mention. The South African workers had until recently held the view that east-coast fever (*Theileria parva*) could not be transmitted with the blood of infected cattle, but the work of Sergeant and others in North Africa in 1927 led them to carry out further observations upon this point, with the result that in 24 per cent. of cases it was found that infection resulted from blood inoculation by the subcutaneous and other routes, and that nearly 50 per cent. of these infections ended fatally. Quantities of blood such as 5 c.cm. intradermally, 100 c.cm. intraperitoneally, and 250 c.cm. subcutaneously resulted in infection. From this it would appear that Koch's bodies are by no means rarely present in the general circulation. Further studies have been carried out on the virus of bluetongue, a disease of sheep in certain parts of South Africa. Theiler, in 1905, showed this condition to be due to a filtrable virus in the blood, and found that by passage of the virus artificially through sheep it became so attenuated after the eleventh generation that it could be used with safety as a vaccine. Deaths were reduced from 11 per cent. to less than 1 per cent. For over 20 years Theiler's originally attenuated strain of virus has been used and has reached the fifty-fourth generation. No less than 25,000,000 doses of vaccine (blood) have been issued with eminently satisfactory results. The attenuated vaccine is preserved in a mixture of glycerin, potassium oxalate, and carbolic acid, in which it has shown remarkable longevity. In the present report it is pointed out that Theiler's work has been fully confirmed and a new strain of the virus has been attenuated for field use. Vaccine preserved as described has been found alive after 18½ years at room temperature, though its antigenic properties were somewhat weakened. This illustrates the remarkable resistance of this virus, a feature also of the virus of South African horse sickness.

The articles upon botulism in animals and birds in South Africa are of interest alike to the medical and veterinary research worker. Botulinus type organisms have been shown to be widely distributed in the soil in South Africa, and the types found by Robinson are considered by him to be the types D and E (Weinberg), though, as he remarks, it seems inconceivable that types A and B can be absent from South Africa when they are known to have such a ubiquitous distribution in other countries. Cases of human botulism have not so far been recorded in the country; botulism has, however, been found in cattle, horses, and birds in South Africa. In cattle the source of the toxin is the bones of carcasses which cattle are induced to eat on account of a phosphorus deficiency in the soil, in horses the source is the carcasses of rats in the fodder, and in ducks the source was not determined. The South African workers have been unable to show that toxin-free bacteria of botulinus type can produce toxin in the alimentary canal of the living animal. Investigations into the life-history of the tapeworm (*Moniezia expansa*) leave the problem still unsolved. There is an interesting account of the pathological lesions attributed to schistosomes in sheep. The article on skin cancer of the Angora goat is a useful addition to the growing literature upon cancer in the domesticated animals. The section of the report devoted to sterility in cows by Prof. Quinlan occupies no less than 222 pages containing 88 illustrations, and that dealing with the breeding of cattle upon phosphorus-deficient veld occupies 107 pages, including 71 illustrations. Three of the longest articles are theses which have been accepted for the degree of D.V.Sc., one of Toronto and two of the South African University.

CONGRESS FOR SEX RESEARCH.

THE second International Congress for Sex Research will be held in London in the House of the British Medical Association, Tavistock-square, W.C., from August 3rd-9th. The preliminary programme provides for general meetings, to be held in the morning, at which problems of present interest will be reviewed by prominent workers. The afternoons will be devoted to discussions on the general papers and sectional meetings. Among the subjects to be discussed at the general meetings are puberty and maturity, problems of the physiology of the sexual glands, and hormone therapy. Membership of the congress is restricted to persons engaged in teaching or research in biology, psychology, and allied sciences and to members of the medical profession. Those who wish to take part are invited to apply to the Congress Secretary, Department of Animal Genetics, King's-buildings, The University, Edinburgh.

THE next session of the General Medical Council will commence at 2 P.M. on Tuesday, May 27th, when the President, Sir Donald MacAlister, will take the chair and give an address.

Dr. Julia Marcella Browne has been appointed medical officer of health for the Metropolitan Borough of Stepney in succession to Dr. Daniel Thomas who died in December last. This is the first time a woman has secured a whole-time post as chief M.O.H., although others have held acting rank in St. Pancras for considerable periods. Dr. Browne graduated in medicine from University College, Cork, in 1917, taking the diploma in public health of the R.C.S.I. in 1920.

THE SIGNIFICANCE OF BLOOD GROUPS.

PART II.*

Testing for Compatibility.

PRACTITIONERS faced with the possibility of being called upon to perform an emergency transfusion are prone to seek some sign of compatibility, but none can be given them. The mixture of drops of the blood of proposed donor and recipient on a slide may produce some doubtful agglutination, more frequently it will merely produce a mess. There is no short cut to the certain determination of compatibility. For a grouping test known sera of Groups A and B and an emulsion in normal saline of the red cells of the proposed donors are required. Whole blood will give rise to trouble from various causes, the principal of which is rouleau formation. The sera may be bought from various commercial houses but as noted last week its titre is always rather uncertain. Sufficient blood for the testing of the donor can be obtained by simple finger prick. The strength of the emulsion does not matter within wide limits; it is my custom to use the red cell pipette of the Thoma-Zeiss haemocytometer and to make approximately 1 in 100 dilution of the blood in normal saline. In the absence of a pipette a couple of drops in two or three c.c.m. of normal saline in a test-tube will serve.

For the actual grouping two plane slides are required; these are marked A and B respectively; one drop of the red cell emulsion is placed on the centre of each of these slides; to the drop on the slide marked A a drop of the A serum is added and to that on the B slide a drop of the B serum; red cells and serum are then thoroughly mixed. In some cases agglutination will appear at once with the appropriate serum;

the rapidity of its appearance depends upon the titre of the agglutinins in the serum and of the agglutinogens in the red cells. In no case is it safe to make a final determination until the preparations have stood for at least ten minutes and it is my custom to allow half an hour. The drops of mixed red cells and serum should be gently agitated before they are examined. It is preferable to examine them with the low power of the microscope but failing this a hand lens will serve; a naked eye observation may fail to identify lesser degrees of agglutination.

In matching two bloods the procedure is exactly the same as for grouping, the only difference being that in matching the red cells of the proposed donor are mixed only with the serum of the proposed recipient. Since matching does not demand the use of sera of known groups, it is in some ways simpler than grouping, and as pointed out above is infinitely preferable on considerations of safety. The difficulty in matching is that it demands the serum of the proposed recipient. For this purpose two or three c.c.m. of blood are required; this quantity can be obtained readily enough, but the difficulty arises in the speedy separation of the serum. With a centrifuge the serum can be separated out in a few minutes and where this apparatus is available the whole procedure of matching can be carried out in half an hour. Where no centrifuge is available, there is nothing for it but to withdraw the blood of the proposed recipient as soon as it becomes evident that a transfusion may be necessary, and to allow the serum to separate out while the donors are being collected. This usually takes an hour or so and by the time that the donors are ready enough serum may be available for the test. Whenever possible, however, the proposed donors should be sent, with a specimen of the serum of the patient, to a properly equipped laboratory and the test should be performed by a person with ample experience of the technique.

Matching is only necessary when the blood is to be introduced actually into the circulation of the recipient. Where blood is to be introduced hypodermically or intramuscularly, as is often necessary in hæmophilia, purpura, melæna neonatorum or other hemorrhagic conditions, the group of the blood introduced is of no importance. Since it is known that the agglutinins do not develop until some months after birth it is also probable that no harm would be done by the introduction of blood without grouping or matching into the circulation of a new-born child, but if possible it is the best plan in all cases where blood is introduced into the circulation to make sure of compatibility.

Medico-legal Applications.

The blood groups have certain important medico-legal bearings. Since the agglutinogens A and B behave as Mendelian dominants, they cannot appear in the blood of the offspring without having been present in the parental blood. From this it follows that their appearance in the blood of a child when they are absent from that of the putative parents, is in itself proof that the relation is not that supposed. This fact has obvious importance in cases of disputed paternity. The field of possibilities under this head has within the last few years been considerably narrowed as a result of the work of F. Bernstein who from mathematical considerations has provided strong evidence for the belief that the whole inheritance of the groups is governed by the existence of the dominant factors A and B, represented by the agglutinogens, and of a recessive represented by the absence of both of them; this recessive, in conformity with the nomenclature used above, may be described as O; according to Bernstein's hypothesis it is allelomorphous to A and B.¹ For practical purposes the position under Bernstein's hypothesis may be summarised as shown in Tables II. to IV.

All the available evidence goes to bear out the correctness of Bernstein's hypothesis, and there can be little doubt that apparent exceptions are due to errors of observation. No case of disputed paternity has yet been decided in the British courts upon the evidence afforded by the blood groups, but such

* Part I. appeared last week.

See THE LANCET, 1928, I., 1182.

evidence has been freely admitted before the German courts and in a number of cases has been decisive. The writer has twice been asked for opinion in cases of disputed paternity; in both cases the evidence afforded by the blood groups was equivocal and was not placed before the court. In placing evidence as to blood group before a court in a case of disputed paternity it is not sufficient to rely only upon tests of the red cells; the serum also must be tested with red cells of known agglutinin content, and in view of the differences of titre

in both agglutinin and agglutinin it is desirable to confirm all results by absorption of a known potent serum of Group IV. with the red cells of the subject. Mere testing of the red cells against known sera of Groups A and B is by no means a satisfactory way of establishing the blood group for medico-legal purposes.

Blood Groups in Criminal Cases.

The determination of the blood groups has certain other medico-legal applications mainly in connexion with criminal practice; thus it may be of importance to determine the group of the blood staining clothing or weapons in cases of murder and wounding. The establishment of the fact that blood stains on the clothing of the accused are of the same group as that of the victim, and different from his own, would be a very strong point for the prosecution; so thoroughly has this been realised on the continent that in certain European countries, of which Russia is one, it is customary to determine the blood groups of all persons concerned with crimes involving wounding. When it is desired to ascertain the group of blood staining clothing or instruments no attempt should be made to remove the blood, but the stained articles should be despatched with speed and with as little disturbance as possible to the laboratory at which they are to be examined.

THE TOXÆMIAS OF PREGNANCY.

EXPERIENCE IN SIAM AND IMPRESSIONS WHILE TRAVELLING.

By G. W. THEOBALD, M.D. CAMB.,
M.R.C.P. LOND., F.R.C.S. EDIN.,

LATE VISITING PROFESSOR OF OBSTETRICS AND GYNECOLOGY IN
THE CHULALONGKORN UNIVERSITY, BANGKOK.

I THINK it is impossible to exaggerate the importance of the contention that any explanation offered for a disease should have a universal application. It has been my privilege this year to travel from Japan through French Indo-China, Malaya, India, Iraq, Syria, and Palestine to Cairo. I visited hospitals in all these countries and in the ports of China, and met and conversed with a considerable number of doctors. There is not the slightest shadow of doubt that the toxæmias of pregnancy are very much less common throughout the East, if Japan be excepted, than they are in the West. Hyperemesis gravidarum is practically unknown in these countries. Accidental hæmorrhage of the toxæmic variety is an exceedingly rare obstetric complication, while eclampsia is much less common than in the West, and usually of a milder type. It is obvious that in such countries accurate statistics are not available, and opinions must be formed from the figures of isolated hospitals and from the experience of practitioners with whom one comes into contact. A letter received from Colonel Graham, I.M.S., Public Health Commissioner with the Government of India, states that the statistics I requested, showing the incidence and distribution of the toxæmias of pregnancy in India, are not available. It would be of great value if some responsible person could spend the time travelling and collecting such statistics as are obtainable in these countries.

Three Years in Bangkok.

I can speak with more authority on the incidence of these diseases in Siam. I have met nearly all the missionary doctors in the country, and they are emphatic that all the toxæmias of pregnancy are very rare. Not one doctor had ever seen a case of toxæmic accidental hæmorrhage, and I could only hear of six cases of eclampsia in their united experience, most of the doctors never having seen even one case. No system of purdah obtains, and if these diseases existed the doctors would most assuredly be cognisant of them. Bangkok is a city of some 700,000 inhabitants. I was for nearly three years in charge of the largest obstetric service in the city, larger than all the other obstetric services in the country put together. I did not see a single case of toxæmic accidental hæmorrhage.

The following list comprises all the toxæmic cases that I saw.

1. There were seven, possibly eight, cases of eclampsia, but only four had fits in the hospital.
2. Seven patients suffered from a severe grade of anaemia, presumably aggravated by the pregnancy, but only one from the pernicious type.
3. Two fatal cases of toxæmia were associated with hydatidiform moles. One of these patients suffered from hyperemesis gravidarum, and the other had anuria.
4. Two fatal cases of toxæmia were associated with mania early in the pregnancy; neither of them came to autopsy. It is just possible that these patients suffered from malignant malaria.
5. I saw, in consultation, one case of hyperemesis gravidarum in a wealthy neurotic Siamese woman. The vomiting was completely checked, but the patient nevertheless died a day or two later. No post-mortem examination was permitted. This was the only case of hyperemesis gravidarum associated with a normal pregnancy that I saw in a Siamese woman, although in the same period I was called to see three European women who suffered from

this complaint, although the European population of Siam is so small. No Chinese woman suffering from this complication was admitted to the hospital.

Bathing in Public.

This almost complete absence of the toxæmiæ of pregnancy was very surprising and extremely suggestive. *Prurhæa alveolaris* is the rule rather than the exception in Siam. Practically every patient is infected with one or more varieties of intestinal parasites. Cystitis and nephritis are common. So common is a mild chronic nephritis among the women that I believe it to be an ascending infection from the bladder. They all bathe twice or more often in the day in the klongs or canals into which they urinate and defæcate; the water must be a fine emulsion of bacteria. They bathe in a sarong or panung, which is similar to a wide skirt, which reaches from their axillæ to well below their knees. When a woman wearing such a garment sits down rapidly in the canal there is a very definite pressure of water forced between her legs, and I believe well into her vagina and urethra. I caused a woman, an hour after she had drunk plenty of water, to bathe in a bath in which was a strong solution of methylene-blue. The dye did not stain the thighs or the mucous membrane of the vulva. On urethroscopic examination, however, a distinct jet of methylene-blue was seen to escape from a crypt on the left side of the urethra about $\frac{1}{4}$ inch from the external meatus. It is interesting to notice that Mohammedan women are not allowed to bathe between the hours of sunrise and sunset during the fast of Ramadan, although no such restrictions are placed on men.

Although chronic nephritis is exceedingly common, marked albuminuria during pregnancy is rare. Lactosuria is excessively rare, and was only noted in one out of about a thousand patients whose urine was examined for sugar. In this case the urine only reduced Fehling's solution for two days. Appendicitis is certainly relatively very uncommon, while disease of the gall-bladder of any kind whatsoever apparently does not exist among the Siamese. The Siamese eat three meals in the day. Their diet consists of rice, cooked vegetables, a little fish, usually salted, and a little pork perhaps once a week. The wealthier classes in the cities are tending to eat more meat. As a race they do not suffer from constipation but rather from diarrhœa caused by the intestinal parasites. Contrary to the statements made by theoretical enthusiasts, the people living in the most primitive parts of Siam have their bowels opened only once in the day, and usually in the morning. The climate is always fairly warm and the clothes are so convenient that a woman can defæcate at any place at any time of the day. The world is her privy and her panung is her closet.

Simple Life.

Their clothes are light, frequently changed and washed, and allow a generous portion of the body to be exposed to the beneficent rays of the sun. They almost live in the open air. The children run about naked until they are 4 or 5 years of age, the little girls merely wearing a silver or gold sporran. There is a complete absence of worry and haste, partly accounted for by the Buddhist doctrine and partly by the ease of living in a generous country in the tropics. A little rice, a few vegetables, a little tobacco, a home-spun cloth, a house that can be built in a few days—these are all the wants of the peasants who live to-day in the same way as their forefathers did a hundred years ago. Their diet is obviously deficient in vitamins A and B, as vesical calculi and beri-beri are very frequently encountered. The good effect of sunlight can be gauged by the fact that rickets is practically unknown, and I have not seen one flat pelvis in a Siamese woman. There is one other article of diet that must be mentioned. The Siamese constantly eat lime with their betel or areca-nut. This may provide the women with the necessary calcium, for they never drink milk and there is certainly not much calcium in their food.

The Ports of China.

In China I visited Shanghai, Hong-Kong, and Swatow. Gall-bladder disease, appendicitis, cancer of the intestines, and the toxæmiæ of pregnancy appear to be very uncommon in Southern China. A doctor who had been for 20 years in charge of a hospital near Amoy, in which 20,000 patients were treated annually, told me that during the whole of that time there had only been one case of appendicitis in a Chinese patient living on a Chinese diet. The figures of the Margaret Williamson Hospital, Shanghai, the largest hospital for women in China, suggest a higher incidence of these conditions in Shanghai than in Siam or Southern China. The women there, however, do not live in the same simple manner as in the country. They buy sweetstuffs and cooked foods from the itinerant hawkers who parade the streets all day and well into the night, and are very constipated. The climate is very cold during the winter months and the women wear thick clothes, which are not frequently washed or changed. Moreover, it must be remembered that human urine and feces have a distinct commercial value in China, and a Chinese woman will resist the temptation to pass feces until she can deposit it in her family store, when her nitrogen can either be sold or used for the household gardens. This reticence in a large city tends to favour constipation. Then, too, the Chinese trousers are not so convenient as the Siamese panung.

India and the Nearer East.

In India the toxæmiæ of pregnancy are not common, but their distribution is interesting. The large cities appear to provide a higher percentage of cases than the country areas in which the vast majority of Indians live. This increased incidence in the cities is probably universally true. *Eclampsia* is fairly common in Southern India—i.e., Madras and Bangalore. There were only ten cases of accidental hæmorrhage recorded in the three annual reports that I have of the Madras Government Maternity Hospital, although there were in that time over 8000 deliveries. Moreover, 10 per cent. of the patients treated were Europeans and Anglo-Indians. I visited the large Lady Hardinge Hospital for Women in Delhi, and they had not had a case of eclampsia or accidental hæmorrhage for over 12 months. Osteomalacia, however, is very common there and in the north-west of India; it only affects those women who live a very secluded purdah life. Anæmia is very common throughout the East and is largely due to intestinal parasites, especially the hookworm, which infest so large a proportion of the people. The anæmia is aggravated by pregnancy and is usually of the secondary type. In Bombay, however, anæmia of the pernicious type is frequently associated with pregnancy. This anæmia only occurs during the hot season and is remarkably amenable to treatment by liver extract, whereas the ordinary secondary anæmia is not influenced by this preparation. The diet, climate, habits, clothes, and customs vary enormously in that vast continent. For instance, rice is the staple diet in Southern India, whereas wheat is eaten in the North. No Indian, however, eats much meat. Life there, outside of the cities, is tranquil and the sun shines every day, except in the houses of those unfortunate women doomed to a strict purdah existence.

I visited practically every mission hospital in the Persian Gulf. Not one of the doctors had seen a case of accidental hæmorrhage or hyperemesis gravidarum. Their impression was that eclampsia was distinctly less common there than in America. I visited the excellent new hospital and medical school at Bagdad. They had not had a case of hyperemesis gravidarum or accidental hæmorrhage, and had not lost a case of eclampsia. Dr. Dorman, for many years professor of obstetrics and gynecology in the American University at Beirut, had never seen a case of accidental hæmorrhage, and was of the opinion that it was a text-book disease to be put in the same

category as locked twins. Eclampsia, in his experience, was uncommon and was certainly less frequent during the war when meat was scarce and the diet restricted.

In Jerusalem and Cairo the same emphatic assertions were made about the relative rarity of the pregnancy toxæmias. On the other hand, the surgeons in Jerusalem and Cairo were convinced that appendicitis was on the increase in those cities, and that the increase of cases synchronised with a greater consumption of meat, both fresh and tinned.

Appendicitis in Japan.

In concluding this rapid survey I must refer to the astounding difference in the incidence of diseases between Japan and the rest of the Orient. At one surgical clinic in the Imperial University of Tokyo there were between 80 and 100 operations for carcinoma of the stomach, and between 200 and 300 appendicectomies in the year, out of a total operating list of about a thousand cases. I gathered, from what was told me in Tokyo and Kyoto, that diseases of the gall-bladder, cancer of the intestines, appendicitis, and the toxæmias of pregnancy were as common in Japan as they are in Europe. The large cities of Japan are very similar to those of Europe, although the sanitary arrangements are bad, while the climate is very little better than that of England. The houses are small, badly ventilated, and badly warmed, usually by charcoal stoves. The Japanese lavatories are certainly anything but attractive, and the women are said to be very constipated. The exquisite kimono, while being a thing of entrancing beauty, is certainly not hygienic and denies access to the body to even the most inquisitive rays of the sun. The diet would appear not to be very dissimilar from that of the Chinese and Siamese. It seems to be deficient in calcium, for the Japanese do not drink milk, neither do they chew the betel-nut with lime. They also probably eat more than do the Chinese and Siamese, while the more educated Japanese are tending more and more towards European habits, customs, and diet. Moreover, the Japanese, from whatever angle they are judged, can hardly be said to be oriental in the same sense as the Southern Chinese and Indians.

THE CAUSES OF NEONATAL DEATH.

A STUDY of 800 cases of death within the first 28 days after birth has been made in Glasgow by Dr. J. N. Cruickshank, and his results are published by the Medical Research Council.¹ It has previously been shown that the first week of life is the most dangerous, and in this series 71 per cent. of the infants died within seven days. Of the remainder, 18 per cent. died during the second week, 8 per cent. during the third week, and 3 per cent. during the fourth week. The fact that the maternal death-rate and the first-week infantile death-rate have remained stationary, despite the striking reduction in the later infantile death-rate, suggests the possibility of some connexion between the two. The two main groups of causes of death among new-born infants are injuries or disturbances due to delivery, and illness or infection. A third small group is represented by developmental abnormalities, and a fourth by thrombosis or hæmorrhage associated with maternal toxæmia. Recent work, it is stated, has tended to minimise the significance of environmental influences and malnutrition before birth.

Asphyxia Neonatorum, Birth Injuries, and Allied Conditions.

Group 1.—There were 540 cases in this group, 140 mature and 400 premature. In 51 of them some pneumonic consolidation was found, either by the

naked eye or microscopically; only three of these were mature infants. Many of the children showed birth injuries; 146 had gross intracranial hæmorrhage, and 121 had tears in the dura. The effects of the injury and, to a certain extent, the liability to the injury are increased by the asphyxial congestion present in the new-born child. Sixteen in this group showed developmental anomalies and 15 of them had syphilitic mothers.

Dr. Cruickshank describes these cases as "delayed stillbirths." For some reason or other these children had not succumbed during birth, but had survived in a more or less precarious state for periods varying from a few hours up to three weeks. Fifty-one of them lived on into the second week, but the two which survived this period were exceptional. A certain degree of asphyxia is a physiological accompaniment of the transition from intra-uterine to extra-uterine life and the consequent readjustment of the circulation. Failure to establish full respiration causes atelectasis, a very common accompaniment of asphyxia in neonatal deaths. This is associated with engorgement of the viscera and hæmorrhages. An unexpanded lung with widespread hæmorrhagic oedema is common in premature infants who live for a few days, and affords ideal conditions for the growth of organisms; hence broncho-pneumonia is often superadded. The two main factors which seem to be important in the production of asphyxia are the fact that an excess of carbon dioxide will paralyse the respiratory centre and that the centre may have its vitality diminished by interference with its blood-supply. The theoretical explanation for the establishment of respiration during parturition is that the carbon dioxide tension in the foetal blood is steadily increased during the later weeks of pregnancy, owing to the narrowing of the ductus arteriosus, and finally to the interruption of the placental circulation. The child is thus in a state of partial asphyxia until the respiratory centre is sufficiently stimulated by the carbon dioxide to establish respiration. If, however, the concentration of carbon dioxide is too great, the centre will fail in this task. In other cases the centre may fail as a result of pressure on the cerebral circulation during birth.

Asphyxia produces engorgement of the veins throughout the body, embarrasses the heart, and ruptures small capillaries, causing hæmorrhages of greater or lesser extent. Dr. Cruickshank believes that the underlying asphyxial element is important—even where there are gross injuries—in determining the extent of bleeding. That heart failure plays a significant part in some of these deaths is shown by the fact that withdrawal of blood from the umbilical stump will sometimes revive a moribund infant. Oedema of the brain and meninges is practically always found in asphyxial cases and may be the cause of death.

Neonatal Infections.

Group 2.—Generalised septicæmia—i.e., multiple foci indicating a spread of infection by the blood stream—was found in 120 infants, often in association with pneumonia. Infection before labour must be very rare, but intra-partum infection is probably more important than was once realised. Even in cases of septicæmia it is rare to find inflammatory changes in the stump of the cord, and the portal of entry of the infection is still a matter of conjecture. The infant's skin is very vulnerable, and many cases of sepsis are started by surface lesions, such as pemphigus, eczema, furunculosis, intertrigo, and napkin rashes. Owing to the difficulty of deciding whether a pneumonia is primary or secondary, it is hard to estimate the relative importance of the respiratory tract. Inhaled infection undoubtedly causes many cases of pneumonia in babies, and many of these children die with generalised septicæmia. Infection by swallowing is probably much less common.

¹ Special Report Series, No. 145. London: H.M. Stationery Office. 1930. Pp. 87. 1s. 6d.

The Lesions found Post Mortem.

In asphyxia livida the most striking feature is the venous engorgement with petechiae and extravasations. In asphyxia pallida there may be no congestion, but the distribution of blood does not follow the same laws as in adult shock. Developmental abnormalities were rare and most of the cases of supposed congenital heart disease are probably cases of asphyxia livida. There was never any myocarditis or endocarditis, even in septicemic cases; small hematomata may simulate vegetations if the valves are not examined histologically. Pericarditis was found in six mature and seven immature infants. Pneumonia was the commonest lesion appearing in 197 cases, and in practically two-thirds of all non-asphyxial or atelectatic cases. The distribution and spread of the lesions is bronchial but the patches often resemble those of adult lobar pneumonia; the infection more often occurs in incompletely expanded lung, especially in weakly premature children. The respiratory tract often contains liquor amnii and meconium, and this factor undoubtedly predisposes to pneumonia. Two groups of pneumonia are to be distinguished. The histological features of the atelectatic type are: (1) great congestion; (2) irregular expansion; (3) patchy distribution of consolidation and catarrh; (4) associated bronchitis; (5) constant inflammation of the smaller bronchi and bronchioles; and (6) peribronchitis and peribronchiolitis. Plugs of mucus, cell debris, and meconium are often found in the bronchioles, but pleurisy and abscess are rare. Far more numerous were cases of the septic type, where the lung tissue is for the most part fully expanded and only moderately, if at all, congested. Often this pneumonia is associated with general septicæmia. The affected lung tissue is dark red and peculiarly firm; it exudes blood-stained froth, and the bronchi contain mucopurulent exudate. Pleurisy and abscesses are often present.

Alimentary Disturbances.

Infections of the gastro-intestinal tract were rare in this series, even after a history of diarrhoea and vomiting. These symptoms are probably associated rather with a general disturbance of nutrition or a toxæmia. There were no cases of gastric ulcer and only one of duodenal ulcer, but the large intestine was ulcerated in five cases and congenitally enlarged in four. One small premature infant, the child of an eclamptic primigravida, had appendicitis, associated with generalised septicæmia. Peritonitis was present in 21 mature and 23 immature babies. One child had jaundice due to obstruction by a congenital band, and two had splenomegaly.

Central Nervous System.

There was gross intracranial hemorrhage in 101 cases, 86 per cent. of whom died within the first week, 30 per cent. during the first day. Twenty cases showed some form of infection, while the remainder died from asphyxia and atelectasis. Five were occipito-posterior presentations, two face and brow, eight transverse, and 38 breech. In 31 the delivery was by forceps, and in 32 more there was some manipulative interference. Capillary oozing was almost universal in asphyxiated infants, and gross bleeding due to birth injury was found in 16.2 per cent. Bleeding above the tentorium may cause no symptoms, but below the tentorium it soon causes pressure on vital parts. In very premature infants the choroid plexus may bleed, and choroid thrombosis is closely related to that type of intracranial hemorrhage which is associated with disease of the mother or sepsis in the infant. Sixty-seven of the infants with tentorial tears were mature and 61 were premature. These cases included four occipito-posterior presentations, three face and brow, six transverse, and 32 breech. Death took place during the first week in 91 per cent. and during the first day in 48 per cent., the cause of death usually being asphyxia and atelectasis. Intracranial bleeding over the spinal cord is rare compared

with intracranial meningeal bleeding, partly because the cerebellum, pons, and medulla act as a sort of valve to block the foramen magnum. The lumbar puncture fluid may therefore be practically free from blood, even if there is much meningeal bleeding within the skull. There is, however, usually xanthochromia. Blood may be found in the cerebro-spinal fluid, on the other hand, as a result of extradural bleeding in the spinal canal.

Meningitis occurred in 33 cases, most of the infants dying between the fifth and the thirteenth day. It was associated with septicæmia in 29 cases and with pneumonia in 12 cases. There were 17 examples of abnormality of the central nervous system.

Renal Conditions, Sepsis, Hemorrhage, Syphilis.

Abnormalities of the kidney included: (1) congestion due to asphyxia; (2) gross hemorrhage due to injury; (3) thrombosis and infarction associated with toxæmia of pregnancy and sepsis neonatorum; (4) degenerations of the tubular epithelium associated with infections and cachexia; (5) developmental abnormalities, such as hydronephrosis, polycystic kidney, ectopia, and calculus (one case). In no case was there any lesion that could be called nephritis, though in some feeble cachectic infants the degenerative changes justified the term nephrosis.

Cellulitis was found in 19 mature and 10 premature infants, and swabs revealed streptococci in ten cases, staphylococci in seven, and coliform bacilli in three cases. Five of the babies were delivered with forceps, three by Caesarean section, and nine others suffered interference during labour. Abscesses were found in ten mature and ten premature infants, including six cases of pemphigus neonatorum, but umbilical sepsis was only found seven times in the whole series. The six cases of pemphigus included in the series were part of an epidemic of 15 cases, of whom seven died from general sepsis.

There were 30 cases of thrombosis; in 11 of these the mother had some form of toxæmia, and in most of the others the infant had septicæmia. Lesions were usually found in the kidney or brain. Ten infants died after severe bleeding, apparently due to a hemorrhagic diathesis; only one of these was premature.

The Wassermann reaction was positive in 26 cases, but spirochetes were only found in six. Thus congenital syphilis is not a common cause of neonatal death. Children of syphilitic mothers, however, are often born prematurely, and seem to be particularly likely to develop sepsis neonatorum. Death was due to developmental defects and abnormalities incompatible with survival in 22 cases.

Conclusions.

Dr. Cruickshank concludes that a very large proportion of "neonatal" deaths occur during the first few days of life. Their cause is to be sought among the causes of stillbirth and the complications of labour, which cause asphyxia livida—an exaggeration of the normal congestion present at birth—and asphyxia pallida, a state of shock often associated with injury and hemorrhage. Prematurity is a potent factor in accentuating the effects of asphyxia and atelectasis. It is often due to ascertainable causes, such as maternal disease or toxæmia, accidental or essential ante-partum hemorrhage, eclamptic drugs, violence, or over-exertion. Infantile infection is usually acquired in the postnatal period; important predisposing factors are prematurity, asphyxia, and atelectasis, and the commonest portals of entry are the skin and respiratory tract. There is a tendency to generalised septicæmia.

Preventive measures, therefore, should include an attempt to reduce asphyxia and birth injuries by improved antenatal supervision and greater facilities for antenatal examination and the indoor treatment of obstetrical cases. Other factors are better education of medical students, graduates, and midwives; the reduction of prematurity by more stringent control of eclamptic drugs, and the reduction of neonatal

infection by improved hygienic and housing conditions, and the provision of more hospital accommodation with adequate nursing staff.

Recent Advances in the Treatment of Asphyxia Neonatorum.

In an appendix Dr. Cruickshank sums up as follows the main points in the treatment of asphyxiated new-born infants: (1) the avoidance of all violent attempts at resuscitation; (2) the provision of absolute rest, warmth, and quiet; (3) the immediate toilet of the air passages so as to remove mucus, meconium, and liquor amnii; (4) the supply of oxygen together with 5 per cent. carbon dioxide in regulated doses; (5) the withdrawal of cerebrospinal fluid in cases of high intrathecal pressure and intracranial bleeding; (6) the maintenance of an adequate fluid intake by gavage until the infant is able to take the bottle; (7) care of the skin and accessible mucous membranes, but the avoidance of bathing until normal breathing and sucking power are established.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

Registration of Dentists in Bombay.

A BILL for the registration of dental practitioners in the Bombay Presidency has been drafted by the Government, and is now under consideration. The Bill provides for the establishment of a dental board, composed partly of members of the medical council, partly of dentists, the board to be associated with the medical council, which would exercise disciplinary powers over dentists as well as medical practitioners. Following the British precedent, provision is made for the registration, at the outset, of dentists who hold no diploma but can satisfy an examining body of their fitness to practise. They would be termed simply "dentists," while those who hold recognised qualifications would call themselves "dental surgeons." The draft has been criticised on the ground that it is not advisable for the dental board to be established under the aegis of the medical council; feeling is strong among qualified dentists that it should be an independent body. If Bombay is to have the distinction of being the first presidency to establish a dental register, the credit will be largely due to Dr. J. J. Mody, professor of dentistry at the Grant Medical College, who has worked tirelessly to this end, and has already started a dental hospital. The practice of dentistry in India is chaotic, and it will be uphill work to place it on a proper footing. Not the least of the initial difficulties will be the paucity of qualified practitioners and the absence of facilities for training. With the provision of the essential minimum of hospital and school equipment, however, and granted adequate public spirit amongst the small body of available practitioners, it ought to be possible to make a start. Unlike medicine, with its indigenous *vaid*s and *hakims*, dentistry has no native Indian exponents, apart from the people who call themselves "tooth-binders," and earn a precarious living by ingeniously tying loose teeth to adjoining sound ones. There are, however, already a number of irregular practitioners on western lines who will have to be eliminated.

The Sarda Act.

The coming into force of the Act to prohibit child marriage has aroused much interest. Minor boys and girls have been married in surprisingly large numbers during the last few weeks, in order to forestall the Act, and instances have occurred of children only a few days old being snatched from nursing homes to be united in the bonds of matrimony. The *Times of India* tells of a girl of three, who was sound asleep in bed when her presence was required for the ceremony, and asked on being awakened that it might be put off until the morning. It remains to be seen whether the new ordinance will be defied on a

large scale; a large and influential section, however, of public opinion supports the movement, and experience of other measures of social reform justifies the belief that the measure will eventually be generally accepted as inevitable. An encouraging sign is the enthusiasm of women on the subject. Speakers at the recent All-India Women's Conference in Bombay, and similar gatherings in other parts of the country, have expressed emphatic approval of the Act, and of a Bill which is shortly to be introduced in the legislative assembly to put an end to the practice of dedicating young girls to Hindu temples. At a time when Mr. Gandhi is being denounced as a mere political schemer, it ought to be remembered that the revival in favour of these social reforms is due to propaganda carried on unceasingly by the Mahatma during many years. Child marriage is one of the evils he has constantly attacked.

Vaccination.

It is unfortunate, however, that the Mahatma's recent prejudice against almost everything of western origin has led him to fall foul of important sanitary measures. One of these is vaccination which, of course, plays an even more beneficent part in India than in Europe, and has saved countless lives. It is impossible to argue with him since he attributes many of his views to the promptings of an Inner Voice. The Voice, says the *Times of India*, has now informed him that it is sheer irreligion to resort to vaccination as a preventive against small-pox; it is as bad as eating cow's flesh. This article of faith was recently tested severely when three children belonging to his Ashram near Ahmedabad died one after the other of small-pox, but his conviction remained unaltered. He asks, "if I were to be frightened by these three deaths, of what use would be my faith in God? In the fight that is impending not three but thousands and hundreds of thousands may perhaps have to be sacrificed." And he suggests that this trial has been sent to harden his heart for the civil disobedience struggle.

Bacteriophage in Cholera.

Lieut.-Colonel J. Morison, I.M.S., director of the Medical Research Institute of Shillong (Assam), has had an opportunity of testing d'Herelle's cholera bacteriophage in a hill village epidemic. The outbreak occurred in virgin soil, and the mortality from the first was maintained at a high level, on the ninth day no fewer than seven out of nine persons attacked dying. It is stated that with the introduction of bacteriophage treatment there was at once a change, and Colonel Morison evidently thinks that the treatment was effective. He was associated with Dr. d'Herelle in the early stages of his work in India, and the record of his work in the March issue of the *Indian Medical Gazette* is worthy of study.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Hospitals and Sweepstakes.

THE proposal to legalise the holding of sweepstakes on behalf of charitable hospitals in the Irish Free State has given rise to considerable hostile criticism, and the Bill for the purpose is at present at a standstill. Many religious bodies in particular have been decisive in their disapproval. Last week, however, Sir William Taylor, speaking at the annual meeting of the Coombe Hospital Linen Guild, defended the proposal. He pointed out that, on a conservative estimate, the Dublin hospitals were in debt to the extent of some £130,000. It would take as much more to bring them up to modern requirements. The hospitals had explored every avenue of income, but the fact was that people had not got the money to give. The only means left to the hospitals was the sweepstakes. He did not think there was anything immoral in raising money in this way. Sir William received an unexpected ally in the Very Rev. John

Hannon, S.J., who said that he thoroughly agreed with Sir William's ethical exposition. He knew no ethical reason why sweepstakes should be forbidden; he had nothing but commendation for them if they were not pressed too far. No doubt critics will still ask how, if it is true, as Sir William Taylor says, that people have not got money to give to charity, they still have money to spend on gambling.

The Appeal for Radium.

The Irish Radium Institute, which works in association with the Royal Dublin Society, has recently issued an appeal for funds to purchase an additional supply of radium. Several generous persons have promised guarantees, amounting at present to over £5000, to contribute in equal proportions to sums subscribed in answer to the appeal. It is hoped that at least £12,000 in all may be forthcoming, a sum sufficient to buy one gramme of radium. The radium at the disposal of the Irish Radium Institute is mainly used in the production of emanation which is supplied to surgeons as a therapeutic agent. The Institute rightly takes pride in the fact that the mode of using radium emanation by means of hollow needles, now commonly employed throughout the world, was devised by its workers many years ago. It is to be hoped that the appeal recently issued will meet with a generous response.

A Tribute to Dr. E. C. Thompson.

A tablet has been erected in the Tyrone County Hospital, Omagh, by the hospital board as a tribute to Dr. E. C. Thompson, D.L., who was surgeon to the hospital from 1876 to 1928. The tablet, in addition to appreciative references to his skill, energy, and sympathy, states that "the very existence of the Hospital in its present up-to-date structure and internal condition is largely due to his efforts."

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Health Examinations in New York.

THE first campaign for the promotion of periodic health examinations undertaken by the Five Counties Medical Societies of New York was forecast in a previous letter. It was actually launched last November by proclamation of the mayor. One and a half million leaflets, 21,000 posters, 5000 counter cards were distributed; 30 radio talks and 30 public lectures on periodic health examinations were given; and hundreds of columns of comment appeared in the daily press. The six months' campaign was so successful that a new campaign has been authorised to extend over a full year at a cost of \$30,000. Some new features are now to be introduced. These include an investigation of the health educational work now being carried on by industrial and voluntary associations. It is hoped this to improve the methods of popular education. At the same time an attempt will be made to standardise the health examination in a form that will enable the general practitioner to give the best possible service to his patients. The findings of the research committee will be presented to medical schools in the hope that they may be included in the curricula. To assist physicians in conducting the examinations a monthly bulletin will be issued. Health examination clinics will be held in hospitals and other institutions. The five county societies include a membership of 12,000 physicians.

A Symposium on the Kidney.

The University of Minnesota is organising a short summer course to be held from July 7th-18th on the anatomy, physiology, and pathology of the kidney. No attempt will be made to present the whole wealth of accumulated knowledge on these subjects, but the discussions will rather centre upon recent advances and on those phases of the subject where advance is

most difficult and where intensive investigation is proceeding at the present time. A very strong faculty has been assembled, including, besides members of the university, visiting professors from Johns Hopkins and other universities, and from the Mayo Clinic. Prof. Franz Volhard, of Frankfurt, will conduct a series of clinics. Several evenings have been set aside for round-table discussions.

Causes of Death from Burning.

The New York State department of health has made an analysis of the causes that led to 314 deaths from burning during the year 1928. More than a quarter of the deaths (27.4 per cent.) were of children under 5 years of age and another tenth were of children from 5 to 9 inclusive. Most of the deaths from bonfires and all of the deaths from matches occurred in these two age-groups. The largest proportion of deaths, but not more than 20 per cent., occurred in burning buildings. The following table shows the number of deaths by age as well as by the responsible agency:

Agency.	Total.	Age in years.		
		Under 5.	5-9.	10 and over
Total burns	314	86	31	194*
Bonfires	22	8	—	8
Corrosive substances ..	4	—	—	4
Lamps	3	—	—	3
Matches	14	9	5	—
Stoves	59	11	2	46
Scalds	52	37	4	11
Conflagrations (burning buildings)	91	13	8	70*
Other specified means ..	57	5	6	46
Means not specified ..	12	3	3	6

* Includes two deaths with age unknown.

INFECTIOUS DISEASE IN ENGLAND AND

WALES DURING THE WEEK ENDED

APRIL 26TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox 353 (last week 345); scarlet fever, 1885; diphtheria, 1175; enteric fever, 69; pneumonia, 1014; puerperal fever, 55; puerperal pyrexia, 98; cerebro-spinal fever, 11; acute poliomyelitis, 7; encephalitis lethargica, 7; dysentery, 6; ophthalmia neonatorum, 100. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on April 26th-30th was as follows: Small-pox, 483 under treatment, 31 under observation (last week 512 and 26 respectively); scarlet fever, 2080; diphtheria, 2035; enteric fever, 27; measles, 1055; whooping-cough, 93; puerperal fever, 30 (plus 16 babies); encephalitis lethargica, 110; poliomyelitis, 1; "other diseases," 19. At St. Margaret's Hospital there were 16 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns including London there was 1 death from small-pox, 3 (0) from enteric fever, 125 (58) from measles, 10 (5) from scarlet fever, 30 (5) from whooping-cough, 27 (4) from diphtheria, 48 (15) from diarrhoea and enteritis under two years, and 48 (4) from influenza. The figures in parentheses are those for London itself.

The death provisionally classified to small-pox was assigned to Pinbury (Met. Boro.). (Another occurring in Suncaton U.D. during March has now been returned.) The 3 deaths from enteric fever outside London were reported from Enfield, Bootle, and Sheffield. Fatal cases of measles were still widely distributed, with larger numbers at Salford 6, West Ham and Warrington each 5, Willesden and Darlington each 4. Whooping-cough claimed 4 victims at Liverpool and 3 at Manchester. Death from diarrhoea numbered 5 at Liverpool and 4 at Manchester. Birmingham and Manchester each reported 4 deaths from influenza.

The number of stillbirths notified during the week was 321 (corresponding to a rate of 46 per 1000 births) including 54 in London.

Obituary.

SIDNEY COUPLAND, M.D., F.R.C.P. LOND.,

CONSULTING PHYSICIAN TO THE MIDDLESEX HOSPITAL; LATE
MEMBER OF THE BOARD OF CONTROL.

WE regret to announce the death of Dr. Sidney Coupland, which occurred at his house, Wootton Ridge, Boar's Hill, Oxford, on Tuesday, April 29th, in his eighty-first year, after more than a year of complete invalidism.

Sidney Coupland was born in December, 1849, and was the third son of Mr. W. N. Coupland, of

DR. COUPLAND.

(Photograph by Lafayette.)

Streatham. The family consisted of three sons and four daughters, and the father having met with unmerited business reverses the brothers had to make their own way and coöperate in the support of the family. Sidney Coupland received his early education at Hove House School, Brighton, and proceeded as a medical student to University College Hospital, where the teaching staff included such well-known men as William Jenner, Russell Reynolds, Ringer, Bastian, John Williams, Erichsen, and Christopher Heath. He graduated with honours at the University of London in 1873, and in the next year took the Membership of the Royal College of Physicians and proceeded to the M.D. London. At University College Hospital he held the various resident posts, but he did not wait until a vacancy occurred on the staff but migrated to the Middlesex Hospital, where he was appointed pathologist in 1873, becoming in 1875 assistant physician. On the Middlesex Hospital medical staff he was soon recognised as a sound clinician and an earnest and sympathetic teacher. For a considerable period he was medical tutor in the school, while he edited for four years the medical and pathological reports of the hospital. He lectured on pathology and pathological anatomy and took classes in the wards and out-patient department, where his instruction was recognised as of high practical value. In 1879 he obtained charge of wards, in 1880 he was elected F.R.C.P., and in the following year he delivered the Goulstonian Lectures, which took the form of an elaborate disquisition on anaemia, and in which the general lessons were mostly derived from a study of practice at the Middlesex. He was physician to the Middlesex Hospital for 19 years and during this period he was recognised by his colleagues as a general consultant in the fullest sense of the words. Nevertheless the large range of his clinical work never induced him to write a medical treatise, but his contributions to serial medical literature were considerably numerous, and he published a

brief monograph on endocarditis, and some practical notes on the clinical examination of blood and excreta, which were a résumé in relation to his teaching when conducting the autopsies at the hospital. An appreciation of Dr. Coupland is appended from the pen of Sir John Bland-Sutton, and from this the great influence can be gauged which Coupland exercised at Middlesex as learned physician and sympathetic teacher.

From 1889 to 1896 Dr. Coupland was engaged in making reports on various small-pox outbreaks to the Royal Commission on Vaccination, which it may be remembered took evidence for six years after its appointment in 1889. This work made him thoroughly conversant with every side of the vaccination question, and we owe to Sir William Collins, the only surviving member of that Commission, the following account of Coupland's services, with a testimony to his other fine qualities.

Sir William Collins writes:—"As the only survivor of the Royal Commission on Vaccination which sat under Lord Herschell's chairmanship in 1889-96, I wish to testify to the value of the services rendered to that Commission by the late Dr. Sidney Coupland. He not only investigated with great care and impartiality outbreaks of small-pox at Dewsbury, Leicester, and Gloucester, but he also examined and reported on numerous cases of untoward results alleged to have been due to vaccination. Without fear or favour, but simply as the painstaking and accomplished clinical physician that he was, he recorded the conclusions at which he had arrived, irrespective of the partisan contentions which have always encumbered this much vexed question. He commended the 'sanitary vigilance' at Leicester, and attributed to it the restricted spread and the lower fatality experienced there compared with the cases of Dewsbury and Gloucester, where sanitary conditions and hospital provision and organisation were less satisfactory or less adequate. He classified the injurious results from vaccination into those due to the quality of the lymph, those caused by septic infection, and a third category described as 'cases of deranged health, and even serious symptoms evolved by the constitutional disturbance induced by vaccination in weakly or predisposed subjects.' In reference to these latter he suggested that 'unless small-pox were prevalent at the time it might often be preferable to defer vaccination for several months than to adhere too rigidly to the statutory age, irrespective of the condition of the child and its surroundings.' He also deprecated 'the vaccination of very young infants, as is the practice in regard to workhouse children and those born in lying-in institutions.' The relaxations of the compulsory law which have resulted from the Commission's labour were, it is understood, in harmony with the conclusions at which he had arrived.

Besides his official association with Dr. Coupland it was my privilege to enjoy his friendship for more than 40 years. Coming from a Liberal, non-conformist stock, he was alike in professional and other matters ready to listen to any opinion, but determined to judge for himself. Like his brother, Dr. W. C. Coupland, he brought a broad philosophic outlook to bear on all the problems which he encountered, and if from a rather diffident manner casual observers might misjudge him, to those who knew him well he was a true-hearted friend of firm and sterling quality. He was, moreover, a deeply religious man, though devoid and disdainful of affected piety, and he was successively the admirer and supporter of the Rev. Stopford Brooke and of the Rev. John Hunter, of Glasgow."

It was characteristic of Coupland that he should do the spade-work in connexion with movements in which he was interested, and bodies to which he belonged. Thus he was at different times hon. secretary to the Pathological Society, the Clinical Society, and the Epidemiological Society, and occasionally contributed to the debates, always pertinently though with an air of wishing to conceal his knowledge.

On the fulfilment of his period of office as full physician to the Middlesex Hospital he was elected consultant physician, and was simultaneously appointed a Commissioner in Lunacy. This post he held from 1898 to 1914, when, on the institution of the Board of Control, he became a member of that Board, finally retiring from the service in 1921 after a period of more than 20 years' work in the department. One year later Coupland delivered the Harveian Oration before the Royal College of Physicians of London, when he divided an eloquent discourse into two parts; in the first he revived the personality of Harvey for the audience through the reminiscences of Aubrey, while in the latter part of the Oration he dealt with modern progress in the treatment of the insane and the more intelligent study of insanity which marks the psychology of to-day. Probably it was Coupland's high sense of the responsibility of an official position which prevented him recording any of his experiences while in State employment, just as, save in the columns of THE LANCET, he made no public mention of his investigations intended for the Commission on Vaccination. But in the Harveian Oration will be found an eloquent plea for the removal of the stigma which attached, and which still attaches, in the popular mind to the mental patient, insisting on the ill influence of such prejudices as they stand in the way of the diagnosis, and thus of the cure of the early phases of mental disease.

To this brief epitome of Coupland's valuable career a record must be added of his intimate connexion with THE LANCET. Coupland formed the fourth of a small body of advisers who took over the conduct of this paper during the long illness of Dr. James Wakley, the other three being Sir John Tweedy, Surgeon-General Marston, and James Grey Glover. James Wakley succeeded his father, the founder of THE LANCET, in the editorial chair while still a young man, and throughout his career was particularly dependent on his staff. During the closing years of James Wakley's life, and for the next ten years, Coupland was the principal adviser on medicine generally to the succeeding editors, Thomas Henry Wakley and his son the third Thomas Wakley. In that capacity his industry was as noticeable as were his discretion and his wide range of knowledge. He wrote with facility and clearness and especially with a full sense of the importance of the judgments which he was asked to make, and his leading articles form a résumé of clinical progress in the 'eighties and early 'nineties, while his critical estimates of medical literature were rarely found at fault.

Sir John Bland-Sutton writes:—"The death of Sidney Coupland, my friend and former colleague at the Middlesex Hospital, recalls the condition of staff appointments in London hospitals and medical schools 50 years ago. Coupland was trained at University College Hospital, and like many of his friends elected to come to the Middlesex Hospital, where in those days the teaching appointments in the school were held by members of the hospital staff. The apportioning of the lectureships was made on definite lines. In medicine the physicians taught the principles of medicine, the assistant physicians made the post-mortem examinations, taught pathology, and were, each in turn, curators of the museum. I first met Coupland in the post-mortem room, and our relations soon became close. I attended the dead house regularly because he took great trouble in demonstrating the specimens, and in those early days of my hospital career—before surgeons had become familiar with abdominal surgery—the revelations post mortem were of the utmost advantage to men keen on diagnosis. Coupland was not only skilful in conducting an autopsy, but being curator of the museum he prepared specimens exceptionally useful for teaching purposes, or of intrinsic interest for permanent preservation. In this indirect way I obtained special experience in museum technique. Coupland, like his immediate predecessor, William Cayley, was keen in studying cardiac lesions—

inherited or acquired—and added a fine series of hearts with valvular lesions to the museum. He did not preserve specimens simply because they were rare, but always with an eye to their utility for the lecture room and for class purposes. In addition, he described the specimens and added the clinical notes in his peculiar but perfectly legible handwriting in the museum catalogue. The same care that he devoted to the pathological department he manifested in the wards.

He was a sound physician, without bombast or conceit; he taught his clinical classes the methods of investigating a 'case,' the manner of using special instruments, ophthalmoscope and laryngoscope, as well as the stethoscope, how to conduct the microscopic examination of urinary deposits, and the estimation of sugar, and the significance of the findings. Being specially interested in the problems of anæmia his clinical clerks soon became expert in the methods of counting blood corpuscles. Anæmia and leukaemia were disorders in which he took great interest. Thus Coupland's practical classes in the wards were of the greatest service to the students. He was most patient in teaching, whether it concerned clinical examination, note-taking, or writing prescriptions. A gross blunder on the part of the student did not evoke any rude outburst or banter, but simply a peculiar nervous titter! In respect of surgical treatment he was progressive, and the surgery of cranial, thoracic, and abdominal diseases equally attracted him. In 1880 he had a young woman under his care in whom he diagnosed a renal calculus, and induced his surgical colleague, Henry Morris, to remove the stone. The surgical intervention was successful. This 'case' is historical; it laid the foundation of renal surgery as we understand it to-day. I was present at the operation, and M. M., the patient, lived many years, and reported herself at the hospital from time to time. As the years rolled on I became Coupland's co-relative surgeon in the hospital, and I remember that he transferred a groom to my ward with an 'iliac swelling.' I operated on the man and removed his vermiform appendix; this was the first example of 'appendectomy' in the history of the Middlesex Hospital.

Sidney Coupland, conscientious as a teacher, was highly self-conscious as a physician; his apparent timidity was inimical to success in dealing with private patients, especially female patients. He disliked strife, was loyal to his colleagues, and devotedly attached to his adopted hospital."

Dr. Sidney Coupland married in 1880 Bessie, daughter of the late Mr. Thomas Potter, of Great Bedwin, Wilts, who survives him at the age of 83, and within measurable distance of their golden wedding. Their marriage was one of unbroken devotion. Prof. Reginald Coupland, Beit Professor of Colonial History at Oxford, is the only surviving son, an elder brother having died as a child from diphtheria, to the abiding grief of the parents.

MURDOCH CAMERON, M.D., C.M., LL.D. GLASG.,
LATE REGIUS PROFESSOR OF MIDWIFERY AND DISEASES OF
WOMEN, UNIVERSITY OF GLASGOW.

WE regret to announce the death of Prof. Murdoch Cameron, which took place on April 28th in a nursing home in Glasgow in his eighty-fifth year.

Murdoch Cameron, the son of a merchant in Glasgow, was educated at his native University, where he graduated in medicine in 1870, proceeding to the M.D. degree two years later. He made midwifery a study from the beginning of his career, his first post, which was obtained over 50 years ago, being that of physician to the University Lying-in Hospital. In 1878 he was appointed physician accoucheur to the Western Infirmary, having in the meantime become assistant to William Leishman, the well-known Regius Professor of Midwifery in the University, and father of the late Sir William Leishman. In 1888 Murdoch Cameron obtained

the appointment with which his memory will always be associated, namely, that of obstetrical physician to the Glasgow Royal Maternity Hospital, and it was here that he made his reputation as a progressive obstetrician. He found a large and varied clinical field the cultivation of which gave exercise to his boldness, ingenuity, and practical learning. His name was closely associated with

Cæsarean section, owing to certain successful operations conducted upon rickety subjects 40 years ago, the introduction of antiseptics allowing for the revival of procedures which had been abandoned because of their fatality; here Cameron's actual training under Lister at the Royal Infirmary—a fact which he recorded in the Lister Centenary celebrations—stood him in good stead.

In 1894 he succeeded to the chair of

PROF. CAMERON.

[Photograph by Annan.

midwifery in the University on the resignation of Prof. Leishman, and occupied the post till 1926, having therefore been engaged in lecturing to succeeding generations of students, first as assistant and then as full professor, for over 40 years. The authorities of the University recognised the distinguished nature of his services by bestowing upon him the degree of LL.D., and he was elected honorary President of the first International Congress of Obstetrics and Gynaecology which was held in Brussels in 1892.

An official visitor to the Glasgow Royal Maternity Hospital has sent us this vivid recollection of Cameron within the walls of the institution where he spent so much time, and spent it so valuably. He writes:—"The occasion was an annual meeting of the Maternity Hospital Board. Cameron was there waiting to show me over the hospital and I could see that every stone of the building had a significance for him. His real life had been lived there and the structure took, for me, an almost personal meaning as he held forth on its history, explained its development, and showed photographs of early cases. Among these were three cases of Cæsarean section, the first, I understood, to be done in the hospital, if not in Glasgow. The awful history of maternal rickets in Glasgow later made the operation frequent when Cameron's pioneer message was understood. Cameron was full of enthusiasm, which age had not abated (and he was no longer young). When we came to the room where the new-born were first taken to be handled and dressed, he said, as the nurses were coming in twos or threes: 'That's the music!' and then, like a young resident, explained the method of ordering the new babies and labelling them for restoring to their mothers at the correct moment. It was the talk of a man whose whole soul was touched with the successful management of new life and the preservation of the mother."

Prof. Murdoch Cameron was predeceased by his

wife for over 30 years, and is survived by one son, Dr. Samuel Cameron, who is obstetric surgeon to the Glasgow Maternity Hospital, and four daughters, one of whom, Dr. Agnes Cameron, is physician to the Stobhill Hospital, while another daughter is matron of the Stirling Maternity Hospital.

EDWARD LAW, M.D. EDIN.,

CONSULTING SURGEON TO THE LONDON THROAT HOSPITAL.

WE regret to record the death of Dr. Edward Law which occurred at Hove on Wednesday, April 30th, in the seventy-sixth year of his age. For many years he occupied a leading place in London as an otologist, and this position was equally allotted to him on the Continent and in the United States. The long period of ill-health which marked his later life has, perhaps, obscured the memory of a distinguished man.

Edward Law was born in 1853, the son of Abraham Law, of Sheffield, and received early education in his native city and his medical training in the University of Edinburgh, where he graduated as M.B., C.M. in 1877, taking the M.R.C.S. Eng. at the same time. After holding certain resident appointments he decided, for health reasons, to accept an appointment as surgeon in the Pacific Steam Navigation Company, and later became a medical officer in the Orient and City Lines, making up a period of some three years in which he was a ship's doctor. He then commenced to practise in Australia, where he resided for two years, at the end of which period, his health having recovered, he decided to return to Europe and to specialise in otology. With this object he spent three years in Vienna where Politzer and other workers along the same line had made their clinics celebrated, and during this period he not only acquired a practical knowledge and expertise that few otologists and laryngologists in this country at the time possessed, but he became a real German scholar and a personal friend of many of the professional leaders in the Austrian capital. He returned to England in 1883 and became house surgeon at the Throat Hospital in Golden-square, where Morell Mackenzie was the leading figure, but in 1887 the London Throat Hospital was founded, and Law, one of the originators of the scheme, became a member of the staff.

We are indebted to Dr. E. B. Waggett for the following personal estimate of Law as doctor, colleague, and friend. To the sympathetic picture any addition would be superfluous. "For one of his junior colleagues on the staff of the London Throat Hospital which he had helped to found, the outstanding memory of Edward Law is that he possessed the strange faculty of authority; his dictum upon the prognosis of a case of deafness or upon the desirability or otherwise of operation was accepted without question, and the opinions which he expressed at the meetings of the medical societies were always listened to with respect. To-day with the accumulation of 30 years of research and of clinical experience, coupled with precise methods of scrutiny, it is difficult to recall the nature of personal authority; there is no question but that Law exhibited that faculty, and that fact is evidence that he knew all that was known up to date, that he took infinite pains in arriving at an opinion, that he was a close and accurate observer, and that his judgment was both alert and balanced. As the scope of otological knowledge grew he kept up to date (I have by me now his attempt to render intelligible the elaborate work of Barany on the labyrinth), and until his retirement a year or two before the war Law's opinion was sought and accepted in problems where clinical tests had proved indecisive. In a word, Law was an exceedingly good doctor, with the result that he acquired the complete confidence of colleagues throughout the world, and enjoyed a very large and important practice. For reasons of health he took no active part in the development of operative surgery, although during his time at Vienna he had

gained a reputation for unusual skill with the chisel. This fact, coupled with a disinclination for uninvited self-assertion, probably robs him, in the eyes of the rising generation, of the prominent place which he took as a pioneer of precise otology in Great Britain—a place which is certainly accorded him by the generation which was brought up on his translation and edition of Gruber's 'Diseases of the Ear,' the recognised text-book on the subject in this country for many years.

"If Law was an example of the best type of doctor, the man who devotes all his consideration and all the knowledge available to the welfare of his patient, he was also the best of colleagues and the best of friends. Many of his juniors must be able to recall personal experiences of the working of his generous nature; clinical difficulties surmounted by his unostentatious advice; credit due to his judgment thrust by him upon their shoulders; the confidence of patients restored where cases threatened to go awry. Before ill-health overtook him nearly 20 years ago, Law was vivacious, witty, a good sportsman, and the centre of a circle of close friends both in and outside the profession. All this does not account for the affection he inspired in his closest friends and in a remarkable degree in his old patients. Those who knew him well will agree that in some singular fashion he was a particularly lovable person; he was kindly, courteous, straightforward, a staunch ally, and completely unselfish, but I think that his peculiar attraction must lie in his capacity for loving his friends."

HUBERT JOHN BURGESS FRY,

M.D., B.Sc. Oxfr., D.P.H.

Dr. H. J. B. Fry died on May 5th, having been ill only for two or three weeks. He was a pathologist of standing who for the last eight years had specialised in cancer research and had taken a prominent part in the organisation and activities of the British Empire Cancer Campaign. Dr. Fry was born in India in 1885, and educated at Charterhouse, Magdalen

College, Oxford, and St. Thomas's Hospital. He was a distinguished student, obtaining an exhibition in science at his school and at his college, and taking a degree in natural science with first-class honours in physiology. After graduating he was appointed to a university biological research scholarship at Naples, and worked there at the thesis which gained him his B.Sc. He returned to England and attached himself to St. Thomas's Hospital, whence he graduated in medicine in 1911, taking his M.D. in 1914. He became resident house physician and then casualty officer at the hospital, and served as clinical assistant in four

DR. FRY.

different departments before he specialised in pathology, becoming demonstrator and Jenner Research Scholar, and later assistant director of the pathological department. On the outbreak of the war he joined the R.A.M.C. (T.), and served in France for some time as a regimental medical officer and at a casualty clearing station. He was mentioned in despatches and later was withdrawn to the base to do special pathological investigations, notably in influenza and on the treatment of septicæmia. For four years after the war Dr. Fry worked as bacteriologist in the Central Laboratory of the Ministry of Pensions, and in 1922, when the pathological depart-

ments of the Cancer Hospital, London, were being reorganised, he was appointed pathologist to the Research Institute of this hospital. Realising the importance of reliable tests for the diagnosis of cancer, he began an investigation into the various serological tests which had been described and developed a new flocculation test which gave a high percentage of correct results when applied to cases of cancer. He made no claim that the test was specific for cancer, but with characteristic thoroughness and caution he studied the conditions responsible for the reaction. He found that they were due to cellular degeneration, and could demonstrate that if certain other conditions associated with cellular degeneration, such as syphilis and tuberculosis could be excluded, the test was a valuable aid to the diagnosis of cancer. The advances made by the experimental study of carcinogenesis attracted his attention to the relation of trauma to cancer, and at the International Cancer Conference held in Paris in March, 1930, on the occasion of the opening of the new cancer centre in Villejuif, he communicated the clinical material which he had collected bearing on the question of cancer arising in the scars of war wounds. Dr. Fry served on several committees of the British Empire Cancer Campaign, and was largely responsible for organising the International Cancer Conference held in London, in 1928. He was a member of the Editorial Committee of the *Cancer Review* from its inception, and the standing which this journal has acquired during the five years of its existence is largely due to his efforts.

Soon after his appointment to the Cancer Hospital, Dr. Fry left London to settle in Welwyn Garden City, where his wife, Dr. Gladys Miall Smith, started in general practice. He took an active interest in the development of garden city ideals, and was a popular and prominent member of the local community, becoming a J.P. of the county of Herts.

The honesty of his purpose and the charm of his personality endeared Dr. Fry to all who came into contact with him, and wide sympathy will be felt with his widow and children in their loss.

Prof. Archibald Leitch writes:—"Our minds are benumbed by the loss of our dear friend and colleague. Everybody who had any acquaintance with him would realise his outstanding qualities and those of us who were in constant association with him regarded him with affectionate admiration. He seemed to have all the good qualities. Though uncommunicative about himself he had a charming genius for friendship, and though he held strong views on politics and social affairs no one could possibly quarrel with him. He was sincere and he was thorough in everything that he did. It was fortunate for me to gain his friendship during the war and doubly fortunate to get him as a colleague afterwards. His published papers indicate the scope and the extent of his laboratory work but they represent only a fraction of his investigations. He crowded more into a day than anybody else I knew. When there was a temporary lull in the work of the pathological laboratory he filled the time with experiments in the animal room, mainly on immunology, or he made abstracts from foreign scientific literature, or he attended a committee meeting. His life was strenuous but never hurried. The municipal affairs of Welwyn Garden City, where he was a magistrate, occupied some of his evenings. On Saturday afternoons he played football, hockey, or tennis, or he rode a horse; he was an all-round athlete—a good cricketer, a good swimmer. I used to tell him in a chaffing way that he ought to give up Association football at his time of life, for he was 44, but he was physically strong and apparently fit. I wonder if he did not tax his energies too much, so that when an acute illness came it found a tired body. His scientific abilities were great, but far more than that, he was a real man."

The portrait is from a group photograph taken at the Paris conference in March.

THE LATE MISS M. B. WILLIAMSON.

The Royal Society of Medicine owes a debt of gratitude to Miss Williamson, who was attached to its secretariat for over 30 years. It was in 1904 that she joined the permanent staff of the Royal Medico-Chirurgical Society under Sir John MacAlister, to whom she had already acted for several years as temporary assistant. Three years later the Royal Society of Medicine was founded, and through the crowded and difficult times of preparation, negotiation, and completion Miss Williamson was the right hand of the secretary and honorary officers. Again in 1911, when the new house at 1, Wimpole-street was being built, and in the following year when the books and other effects were being transferred there from 20, Hanover-square, it was on Miss Williamson that the organisation fell. And finally, when in the war period of 1914-18, many of the staff and honorary officers were on active service, her unflagging energy and cheerfulness carried through tasks which might well have discouraged a less ardent spirit. In 1925 a special resolution of gratitude and appreciation was passed by the Council for her fine service, and it was fitting that the memorial portrait of Sir John MacAlister should have been unveiled by her hand.

Dr. Donald Davidson's death at Plymouth, where he was port medical officer, cuts short a promising career in the public health service. He qualified from King's College, London, in 1922, and had recently taken the highest medical qualifications. His contributions to the *Medical Officer* showed uncommon wit and wisdom, and his loss is felt among a wide circle of friends.

Correspondence.

"Audi alteram partem."

A UNIVERSITY DEGREE FOR THE GENERAL PRACTITIONER.

To the Editor of THE LANCET.

SIR,—The correspondence in your columns on this subject encourages me to make an appeal on behalf of a smaller band of medical men who find themselves the victims of the very rigid and unreasonable regulations of the London University. Every year a number of colonial students, many of whom have completed their pre-clinical training at a Dominion university, arrive at this world centre to pursue their hospital training. Many of them are unaware of the obstacles that await them in the way of non-recognition of their colonial matriculation or their qualifying examinations in the pre-clinical subjects (I was completely misguided by the dean of one of the largest medical schools in London with whom I had corresponded from abroad), whilst others decide to proceed with the Conjoint diploma, not recognising at the time the full significance of a medical degree, or being forced that way by financial considerations.

The general practitioner feels the loss of a degree only mildly as his patients are little concerned with his academic qualifications, but the would-be consultant and the man interested in public medicine finds an almost insuperable barrier and he is irrevocably doomed to the restricted field of a non-university man. Even the M.R.C.P. qualification which, when combined with the M.B., B.S. of a recognised university, constitutes the open sesame for the more desirable hospital posts is usually quite ineffectual in itself.

That the M.D. London should be attainable on the standard suggested by "M.D., M.R.C.P." would mean a definite lowering of the status of the degree such as would be undesirable. Exemption

from the Matriculation examination and the first and second qualifying examinations, however, could be and should be granted more readily upon presentation of other qualifications or indications of an acknowledged standard, not necessarily university degrees, permission being granted to sit for the final examination for the M.B., B.S. in the ordinary way, from which the M.D. or the M.S. would be obtainable.

Life is too short to allow one to return for two or three years to the dissecting room and the laboratory, but six months of study which gave promise of a university degree of standard would be acclaimed by all who were eager to gain that status.

I am, Sir, yours faithfully,

May 4th, 1930.

M.R.C.P. Lond.

AMPUTATIONS AND ARTIFICIAL LIMBS.

To the Editor of THE LANCET.

SIR,—The report in your issue of April 12th (p. 807) of the discussion at the Section of Surgery of the Royal Society of Medicine is of special interest to those who recognise the value of the opinions of surgeons at Rochampton who have seen the after-results of thousands of amputations. Artificial limb makers will welcome an opportunity of noting the effects of amputation in war cases and comparing them with similar operations in civilian cases. This applies with emphasis to the value of the Syme, Stokes-Gritti, and other operations through knee- or ankle-joint. It was probably impossible for surgeons to give definite statistics of the number of these cases which required reamputation during the succeeding ten years, but in civilian cases the problem is very different. In war cases the Syme amputation was largely a sequel of gangrene from frost-bite, and in the knee-joint amputations there were complications from sepsis. The original amputations were often hurriedly done, involving subsequent operations. In civilian cases, on the other hand, complications are only to be feared in cases of tuberculosis, and at the present day the trouble is generally eradicated in the amputation.

From our own records as artificial limb makers, of a hundred cases of Syme amputation we find that not a single case had to undergo reamputation, and the wearers of the limbs are undertaking arduous duties on railways, at the docks, in building operations, and so forth; they continue to wear the limbs for ten, twenty, or more years, without difficulty. We have the same experience of amputations at the knee-joint providing an end-bearing stump; the power to take pressure on the extremity encourages the wearer to engage in tasks which involve long periods of walking or standing. In all these cases we consider it essential that the stump shall fit snugly in the socket at the extremity, as in limbs which permit of a loose movement of the stump, either in the socket or on the end-bearing, there is danger from resultant friction. We consider that, even in the war cases, some of the trouble has arisen from imperfectly fitted limbs or from alteration in the stump after the artificial limb was applied, and that the number of these cases is now very small.

The coöperation and advice of the operating surgeon is of the highest value to the limb maker, and it is by consultation together that the most perfect results are attained.

We are, Sir, yours faithfully,

W. R. GROSSMITH, LTD.,

12, Burleigh-street, W.C., April 26th, 1930.

A POSTAL WORKERS' BED.—Postal workers in all departments between Durham and Berwick-on-Tweed have collected £1000 for the endowment of a bed in the Royal Victoria Hospital, Newcastle-on-Tyne. The money has been provided in three years by voluntary deductions of pence from the wages of the contributors.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

DEBATE ON THE MINISTRY OF HEALTH VOTE.

Mr. Greenwood's Introductory Speech.

ON Tuesday, April 29th, the House of Commons went into Committee of Supply on a vote of £12,724,200 for the salaries and expenses of the Ministry of Health. Mr. R. YOUNG in the chair. The early part of a speech by Mr. ARTHUR GREENWOOD, Minister of Health, in introducing the vote, was reported in THE LANCET last week. Mr. GREENWOOD continued:

THE HEALTH SERVICES.

Maternal Mortality.

Unfortunately the problem of maternal mortality remained and during the last five years there had been a slight increase in the rate. That was serious. A special committee has been appointed by Mr. Neville Chamberlain when Minister of Health to consider this complex problem, and that committee had, among other things, been examining in detail individual maternal deaths, and out of that investigation he believed new light would come bearing on this subject. He hoped that within the next month or two the committee would issue an interim report. The Departmental Committee appointed to consider the working of the Midwives Act, with special reference to the training of midwives, reported not long ago, and their main recommendation was that a national maternal service should be instituted based on insurance principles under which necessary medical services should be provided as part of the medical benefit under the National Health Insurance Act; and the aim of the service would be to provide for more women proper attention during confinement with a view to reducing the rate of mortality. These matters were now under the consideration of the Government with a view to devising a scheme of maternity service which would have due regard on the one hand to maternity benefit under the Insurance Acts, and on the other to the services provided by local authorities under the Maternity and Child Welfare Act; for he was convinced that this complex problem would only be solved by utilising every means at their disposal.

Tubercle and After-care.

With regard to tuberculosis it was good to know that there was still a declining death-rate but more remained to be done. It was clear that a great deal had been done by sanatorium treatment and that more or less permanent cures had been effected and people after full treatment had been able to resume normal life and employment. But, unfortunately, in many cases a patient who had had sanatorium treatment could not well go back to the rough-and-tumble of ordinary life and ought to lead a sheltered life for a period. No doubt in most cases he had no financial resources, and unless cared for there might be a relapse and he might become a source of infection. In the past the tuberculosis campaign had had two objects in view; in the first place, the prevention of infection by the earliest possible discovery, and secondly, the provision of adequate treatment with a view to a cure of the disease. In the Public Health (Tuberculosis) Act, 1921, power was given to counties and county boroughs to make arrangements for the after-care of persons suffering from tuberculosis. Something had been done but the fact that treatment seemed to be more urgent and that hitherto expenditure on after-care did not rank for grant as provision for treatment did, had no doubt deterred local authorities from making after-care provision.

The time had now arrived to press this question of after-care a little further. The financial provisions of the Local Government Act had obliterated any distinction between grant-earning and non-grant-earning services of local authorities. The fact also that public health authorities, county councils, and county boroughs were now public assistance authorities would lead them to see that it was cheaper in the long run to do all they could to restore people suffering from tuberculosis to the funds of the public assistance committee. Something had been done by means of village settlements, a few of which existed in this country, the two most important being the settlement of Popworth, in Cambridgeshire, and Preston Hall, in Kent. The primary object of these establishments was to provide tuberculosis

patients who had had treatment at a sanatorium with remunerative employment suitable to their physical condition and regarded as part of the cure, and as a means of bringing them back to a position of relative economic independence. These settlements had been more or less successful. There was a hospital section where cases are studied, where they were passed into the sanatorium when ripe for treatment, and where a certain amount of training could be undertaken under strict medical supervision. Then there was the training section where patients were sufficiently recovered for them to undertake definite instruction as part of their treatment, as well as with a view to fitting them for the industrial section of the settlement, and there was the industrial side of the settlement where a man had sufficiently recovered to work, say, six hours a day, and where he could not be driven but where he could employ himself for wages on work suited to his physical condition, where he could be watched and removed if his condition became worse. Those experiments were hopeful, and the experience of the existing settlements and the principles on which their successful working depended had been brought within the last few months to the notice of certain local authorities where, it seemed to him, conditions were favourable to the successful establishment and maintenance of similar establishments. He hoped that before very long the number of village settlements for tuberculous persons would be increased. Even if they were able to provide settlements for all those for whom settlements would be appropriate, they would still be left with a number of people who would require after-care, following on sanatorium or other treatment. He hoped that the local authorities, as the next move in the campaign against tuberculosis, would consider and experiment in methods of after-care for tuberculous persons.

THE POST-GRADUATE MEDICAL SCHOOL.

Less than three weeks ago he had announced in the House that the Government had agreed to make a contribution of up to £250,000 for buildings in connexion with the proposed post-graduate hospital and medical school, and although no money was being asked for under that head, in the present estimate, it seemed necessary to say something about it. The Government contribution was for the buildings, but increased grants would in future be given through the University of London when the school became a recognised school of that university. The publication of the scheme had been received with unanimous approval in both the lay and the medical press. He had since communicated with the London County Council and the University of London in order to get their cooperation in the scheme. That cooperation was necessary, and he hoped now, that in a very short time, they would have completed the next step in the process by the appointment of a fully representative committee representing all the various interests concerned, to consider the very complex problems of planning and administration and so on which must be solved before the scheme could be brought into operation. He believed that this was, perhaps, the most important single step which this country had taken in the interests of public health since the passage of the original Health Insurance Act, because, not only would this be a centre for post-graduate teaching for people from other parts of the Empire, but it would enable the general practitioners of this country, including the 16,000 panel doctors who served the State under the National Health Insurance Act, to have the chance, which they did not enjoy to-day, of keeping in touch with the rapid developments and changes which were taking place day by day in the art and the science of medicine. One looked forward to seeing after it had been at work a great improvement in the service which the medical profession would be able to provide for the people of this country.

Dr. VERNON DAVIES: Will the total expense of the post-graduate course be borne by the medical men themselves? Mr. GREENWOOD: No; I hope that we shall have a certain amount of provision made to assist them. Proceeding, the right hon. gentleman referred to the question of psittacosis. In this country up to the present time they had known 115 cases of which 22 had been fatal. All of them were not associated with the importation of South American parrots; some of the cases were associated with African parrots and others even with love-birds. On account of the seriousness of the problem the Ministry in February issued a memorandum giving advice and suggestions to the public and arranging for cooperation between the medical officers of health and the medical officers of the Ministry in investigation work. The work had been going on and a comprehensive report on the whole question was now being prepared in the department. Meanwhile, events had made it imperative that action should be taken under the Public Health Acts to prohibit the importation of parrots for the time being. The date, May 20th, had been fixed in order to give sufficient time to warn people who might be on the point of importing parrots

DISCUSSION ON THE VOTE.

Sir KINGSLEY WOOD said that he did not think Mr. Greenwood had shown a sufficient grip of the present position in regard to the National Health Insurance Scheme. It was a matter of considerable anxiety to the approved societies and the many thousands of administrators engaged in the work.

The Position of National Health Insurance.

The position was, he said, so serious that if it was continued it would undoubtedly threaten the surpluses of the approved societies and the additional benefits, and particularly the hope of an expansion of benefits in the future. He (Sir Kingsley Wood) did not say that the finances of the scheme were not in a thoroughly strong position and that they had not large reserves—he thought the surpluses at the last valuation amounted to some £85,000,000—but it was a very surprising thing that they should have this revelation given in very impartial terms by the Government actuary of the very great rise in these claims. He did not think it was an exaggeration to say that during the term of the National Health Insurance Act no less than £100,000,000 had been spent on medical treatment and attendance during 17 years; and when they remembered that nearly £500,000 was being disbursed each week in cash benefit, that nearly £2,250,000 per annum was being expended on drugs, and that some 15,000 members of the medical profession gave 60,000,000 attendances every year to insured persons, it was a most surprising thing that they should have this statement of the Government actuary. There was another very serious side to the matter. It was particularly surprising when one recalled the great improvement in national health generally. There had been a very remarkable decrease in infantile mortality; he thought that in 1928 it was the lowest on record. The same thing could be said of the tuberculosis death-rate, and he thought it was Sir George Newman who said that 1928 was, perhaps, the healthiest year in the history of this country. Notwithstanding all that they had a record in regard to sickness and disablement claims which, in the words of the Insurance Comptroller, constituted “a challenge to all who are responsible for the welfare of the scheme.” It was doubly a matter of anxiety because these increases had been continuing for so long. He noticed that in connexion with the percentage of claims to expectation in 1921, the sickness benefit claims for men were 70, and in 1927, the last available date, they had risen to 107. The figures in connexion with married women were more surprising still, because in 1921 they were 63, and by 1929 they had risen to 130. The figures for disablement benefit were more remarkable still. In 1921 for married women the figure was 66, and in 1927 it had risen to 171. From the summary of the report they found that comparing 1921 and 1927 the claims of men in respect of sickness benefit had risen by 41 per cent., the claims of unmarried women by 60 per cent., and the claims of married women by 100 per cent. The claims in respect of disablement benefit were even more disturbing. The claims of men had risen by 85 per cent., of unmarried women by 100 per cent., and of married women by 159 per cent. It was doubtless true that there was a changed standard of medical treatment and that there had been influenza epidemics. A comprehensive scheme of national health insurance such as this covered very many cases of poor physique and of persistent ill-health, and undoubtedly the prolonged spell of industrial depression had played its part in these figures, but no one could say that that was the end of the story, or that it by any means accounted for the position in which the national health insurance societies found themselves at the present time.

Lax Certification.

The Minister of Health would have to direct himself, he said, more closely to the position. After all he was mainly responsible for the medical services under the Act, for the approved societies were not concerned in it. They were given no right of interference with the medical profession. One was driven to the conclusion after reading these reports and the statement of the Government actuary that there was a good deal of lax certification. The panel practitioner was in a considerable difficulty; he had to decide when a man presented himself whether he was ill or not, and it was a considerable responsibility to refuse a certificate. It was a remarkable thing, however, and according to the Insurance Comptroller directly cases were referred from the panel practitioner to the regional medical officer, some 55 per cent. to 65 per cent. immediately declared off the fund. That undoubtedly called for some further explanation from the medical men who were engaged in this work. One could not say what proportion of these sickness claims were improper claims, but whatever the amount—and undoubtedly there was an amount—a considerable part was due to the alteration that had been made in the period in which an

insured person was enabled to change his panel doctor. There was considerable danger in the relaxation. Medical men themselves have said, “How can you expect doctors to refuse certification—everyone being human—when they are faced with the position that if a certificate is refused the insured person can immediately go to another doctor?”

Dr. MORGAN: What body of doctors have ever said that?

Mr. PERRY: Surely the right hon. gentleman recalls that we often had numerous complaints from insured persons about the difficulty of changing doctors under the old system.

Sir KINGSLEY WOOD said they had gone to the other limit now. Undoubtedly there could be a considerable improvement without interfering with the proper rights of insured persons. It was a difficult position, but it would be a great deal worse but for the approved society system. He trembled to think what would be the position if they had one big State scheme.

The Reflex of Unemployment.

Sir DONALD MACLEAN said that it was extraordinarily easy to take prejudiced views about the increase in health insurance claims, and to miss the real issue which was raised by the remarkable increase in notified invalidity. On one thing at least they could congratulate themselves, and that was that there seemed to be no likelihood of the insolvency of the Health Insurance Fund. At the last valuation, about five years ago, there was a surplus of £85,000,000, and he had yet to learn that that huge sum had been substantially reduced. He quite agreed with the reasons put forward by the Minister for some of the increased number of claims. He did not deny that advantages were taken in many quarters of the facilities for getting sickness benefit; but following the year 1926, which started a period of great social difficulty for this country with an immense amount of unemployment, they had as an inevitable reflex of it a decline in the vitality of millions of the population. He thought that the attitude taken by the Minister was the correct one. What was required at present was an intensive internal examination into the whole problem by the sub-departments concerned.

Post-graduate Medical Study.

The announcement which was made the other day, he continued, in regard to post-graduate medical study, was one of the most important projects which had been undertaken for many years. The most brilliant medical men in this country had been forced to make a practice of attending what were practically post-graduate schools in Vienna, Berlin, Paris, and one or two other centres on the Continent. Some of them had even attended one or other of the wonderful schools in the United States of America. This country possessed the most capable, efficient and progressive body of medical men in the world. The research work which was accomplished so quietly in this country needed to be much more widely and fully utilised, not only for the benefit of our own practitioners, but for those who wished to come to this country from abroad. When crossing the Atlantic two years ago he made the acquaintance of an American surgeon of the highest standing. He told him he was coming over for six weeks, and was going to France to attend a post-graduate school. He would very much like to have the opportunity of seeing what was being done in this country, but there was no centre to which he could go. Knowing a great many medical men, he (Sir Donald Maclean) was able to put this surgeon on the right track. He went to the Continent, but stayed only a few days, and hastened back to London. He told him afterwards that the time he had spent away from London he regarded as wasted, because here he could obtain the most valuable information, and had seen very remarkable operations and some of the best research work in the world. He (Sir Donald Maclean) hoped that with the hospital arrangements which were being made at Hammersmith they would be able to establish a school the benefits of which would be felt not only here but throughout the Dominions. Quite recently a Committee appointed by the British Medical Association made a tour of Australia and New Zealand. He had received a letter from the immediate past president of the British Medical Association, in the course of which he said:

“On my visit to Canada and my recent tour to the branches of the British Medical Association in New Zealand and Australia—notably the Congress at Sydney as well as at Brisbane, Melbourne, Tasmania, Adelaide and Perth, and again in Ceylon, Bombay and Cairo—I was profoundly impressed by the constantly reiterated inquiries as to the prospects of the establishment in London of well-organised facilities for post-graduate study and research. I believe the scheme submitted will go far to meet this urgent demand from our medical colleagues throughout the Empire—at home as well as overseas—and that in its fuller developments it will constitute London, what she should long ago have become, a world medical centre for post-graduate work of the highest standard.”

Causes of Increased Claims on Approved Societies.

Mr. RHYNS DAVIES said that the first cause of the increase of health insurance claims was the destruction of a million of the fittest men of this country, and the maiming and bruising of millions in the great war. The disabled ex-Servicemen, unless they received a 100 per cent. pension from the Ministry of Pensions, came on the funds of the approved societies. While he agreed entirely in regard to the point which had been made about excessive certification by panel practitioners, there was one thing to be said in favour of medical men, and that was if a patient went to a doctor and complained that he was not well, he (Mr. Davies) knew of no medical man, however eminent, who could challenge that statement. It was alleged that when a young man came out of a university properly trained as a doctor, in order to build up a practice successfully and quickly he descended to issuing certificates in competition with other doctors. That was the allegation; whether it could be proved or not he could not tell.

Dr. MORGAN: It cannot be proved.

Dr. VERNON DAVIES: Of course not!

Mr. DAVIES said that anyhow he could give the medical Members of the House proof from his office that they had a medical certificate stating that a man was incapacitated from work when he was actually dead. How they were going to get over this difficulty he did not know. No committee in the world could do it. The Minister was right in making an investigation by way of a special medical examination. Rationalisation and speeding-up in industry had, in his view, been one of the greatest causes of the increase in the claims on approved societies' funds. He was not sure that societies had a proper system of sick visitation. A strange thing about this scheme was the more drugs people took the longer and oftener they were ill. The number of chemists' prescriptions in Manchester increased from 5,600,000 in 1924 to 2,250,000 in 1929 for approximately the same insured population, and still there were more sick than ever. There was no malingering except in respect of about 1 per cent. of the insured population. When they remembered the epidemics that had taken place almost every year, the lowering of the vitality of the people consequent on unemployment, especially in the mining districts, the effects of the war, and all those forces which were at work, it was not surprising the claims were heavy. But he trusted as a result of the debate they would be able to find out, not merely how to decrease the number of claims, but how to put the scheme once again on a sound actuarial basis.

Mortality-rate Down and Sickness-rate Up.

Mr. MELLER said that Mr. Rhys Davies had contended that as a result of the war there were a number of men maimed in body who would yield to any attack of sickness. If that were true they would expect to find the increase shown somehow in the ages between 34 and 50. But if they referred to the Government Actuary's report they would find that between 16 and 19 the percentage was 14 in 1921 and 24 in 1927. On the other hand, between 35 and 39 the percentage in 1921 was 13 and in 1927 21. They could therefore dismiss war disabilities as the probable cause of the increase. There had been epidemics of influenza and one would have expected in the period 1921 to 1927 some years in which sickness experience would have dropped very rapidly indeed. Instead of that they found the peak of one year becoming the low point of the following year. There was a gradual increase with apparently no reason for it. The Government Actuary showed, not that there had been a marked lengthening of the periods of incapacity, but there had been a broadening of the area of the people who came upon the sickness funds. The mortality-rate had dropped from 13.2 per 1000 in 1918 to 9.0 in 1928. How was it that medical treatment gave that remarkable decrease in the mortality-rate and a remarkable increase in the sickness-rate? Was this country raising a puny race, who in the old days were prepared to throw off comparatively slight ailments and carry on, but to-day were falling at the very suggestion that there was anything wrong? It was said that during the past year some 400,000 cases were referred to the medical referees. Of that number some 46 per cent. either declared off or failed to attend for examination; some 35 per cent. were found incapable of work; and the balance were found capable of work. It had been said by some medical men that the standard of examination of medical referees was different from the standard of examination of medical practitioners. There might be a difference of view between the practitioners and the referees. But it was a sad reflection that over a period of years the percentage of persons found capable of work by the referees had been certified—it might be for days or even weeks—by the panel doctor to be incapable of work. The inquiry which the Minister contemplated might throw some light as to whether there was a discrepancy between the methods adopted by
